A NEW STUDY OF LOBAR PNEUMONIA, WITH DEDUCTIONS FROM AN ANALYSIS OF FIFTY-FIVE FATAL CASES.[1]

BY THOMAS E. SATTERTHWAITE, M.D.,
PROFESSOR OF PATHOLOGY AND GENERAL MEDICINE IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

HISTORY tells us that in ancient times pneumonia was epidemic, and the Athenian plague that occurred in the year 430 B. C. was described as gangrenous pneumonia; and yet Thucydides claimed that it differed from other epidemics of pneumonia, and resembled typhoid fever; being characterized by ulceration of the bowels and excessive diarrhœa. On the other hand, the Black Death, that in the fourteenth century killed two-thirds of its victims, was associated with cough, bloody expectoration, vomiting and diarrhœa, buboes, carbuncles, and petechial spots. So, in the year 1557, during an epidemic that resembled typhus, in France, epidemic pneumonia was prevalent in Belgium. It occurred in September, after violent and cold north winds, and beginning with catarrhal affections was followed by cough and fever, pain in the side, and difficult respiration. Bloody expectoration occurred on the third day. In the year 1600 there was also a similar epidemic. Its symptoms were dyspnœa, cough and bloody expectoration, pleuritic pains, with delirium. The disease was thought by some to be contagious.

In England many epidemics have been recorded as following influenzas, and Sturges (*The Natural History and Relations of Pneumonia*, London, 1876), to whom I am indebted for the instances just cited, gives a number of similar examples of so-called epidemic pneumonia.

In the majority of these instances, however, the diagnosis of pneumonia was not verified by post-mortem examinations, which were rare in the earlier days of medicine; and even when made did not offer very satisfactory data for the modern pathologist; because the terms used were open to various interpretations. We may truly say that epidemic pneumonia does not prevail to any great extent at the present day; but at the same time a certain number of facts either *appear* to, or *do* actually indicate that it is occasionally epidemic. Thus Dr. H. J. Olklin, the inspecting medical officer of Iceland, in his report of an official visit to Iceland, in 1863, described an epidemic of pneumonia that he found prevailing there, and which he characterized as quite dissimilar from any disease he had seen previous to that time; though his experience covered a sixteen years' residence in foreign countries.

It may be true, then, as Dr. Sturges suggests, that the epidemics of pneumonia narrated by him *did* actually occur; the type varying with the locality. Thus, to give an instance, after the winter of 1708–09, in France, an epidemic of pneumonia occurred in the provinces of Languedoc and Provence, but, on reaching England, shaded off into a widespread influenza. I might mention at this point that the late Dr. James Jackson, of Boston, in "Another letter to a young physician" (Boston, 1861), speaks of an epidemic that occurred in New England between 1812 and 1814. It was called, he says, peri-pneumonia notha, typhoid pneumonia, bilious pneumonia, etc. Post-mortem examinations, he tells us, showed that the inflammation was sometimes seated in the pleuræ; sometimes in the lungs; sometimes in the heart; or in two or more of these parts at the same time. The epidemic followed one of spotted or petechial fever. Of quite another character must have been the epidemic described by Dr. Darlington in a recent number of the *Medical Record* (Dec. 8, 1888), where twenty-five cases of lobar pneumonia occurred within ten days in a total of eighty men, who slept in a single room of a large shanty, and where the foul atmosphere and unsanitary conditions of the workmen seem really to have produced an epidemic.

I. ACUTE LOBAR PNEUMONIA.

My paper this evening is devoted entirely to the subject of lobar pneumonia, in its primary and secondary forms, for I shall adhere to the division of lobar pneumonia into two varieties, as maintained by the old French school that flourished in the first half of the present century; though what was then called primitive or primary pneumonia, I shall call acute lobar pneumonia; and what was called consecutive pneumonia shall be called secondary pneumonia.

It is desirable, however, that I should at this point enumerate the principal types of pneumonia, according to my classification, that there may be no obscurity in my meaning as I proceed.

The types are as follows: 1, acute lobar pneu-

[1] Read before the New York Academy of Medicine, December 20, 1888.

A TABLE SHOWING THE CHIEF CLINICAL PHENOMENA IN 100 FATAL CASES OF THE SEVERAL TYPES OF PNEUMONIA.

	Frequency	Sex.	Occupation.	Part of year.	Lung affected.	Extent.	Antecedent diseases.	Cause.	Duration.	Cause of death.	Physical signs.	Expectoration.	Respiration and pulse.	Pain.	Uræmic sympts.	Nerv. sympts	Abscess.	Gangrene.	Height of temp.
1. Acute lobar pneumonia.	35 Mostly in middle life.	Males largely in excess.	No influence as far as out- or in-door life is concerned.	Oct. to June, 75 per ct.	Right lung usually.	Usually in lower lobe.	.....	Exp'sure to cold subsequently.	1 day to 13 mos., 6 to 9 days.	Mostly heart failure.	In about 50 per cent. dulness and bronchial breathing.	Usually red, brown, black, or green.	Very high pulse rate; resp. rate disproportion'ly high	Present in about 58 p. ct.	Present in about 50 p. ct.	In all.	0	2 per ct.	Higest 108°, average 104.3°.
2. Secondary lobar pneumonia.	19 Mostly after middle life.	"	"	Oct. to June, 100 per ct.	Right lung usually.	"	A large variety of diseases.	.....	1 day to 21 days.	"	In about 65 per cent. dulness and bronchial breathing.	"	Pulse rate less high.	Present in about 40 p. ct.	Present in about 60 p. ct.	"	5 per ct.	5 per ct.	Higest 105°, average 103 6°.
2. Embolic lobular pneumonia.	18 At any age.	"	Out door, 33 per ct., in-door, 67 per ct.	Oct. to June, 78 per ct.	Both lungs usually.	Disseminated.	Pyæmia and endocarditis mostly.	Pyæmia, endocarditis, or pyæmia.	1 day to 26 days.	Sepsis, or exhaus'n or heart failure.	Regular signs rare.	"	Pulse rate much increased.	Present in about 5 p. ct.	Present in about 47 p. ct.	"	22 per ct.	.....	Often normal or subnorm. occasionally mod. elev.
4. Bronchial lobular pneumonia.	20 At any age.	"	Out-door, 77 per ct., in door, 23 per ct.	Oct. to June, 75 per ct.	Both lungs usually.	"	Diphtheria, measles, fractures, nerv. dis.	See other column.	1 day to 30 days.	Heart failure mostly.	Regular signs in about 50 per cent.	"	Pulse rate as high as in sec. lobar pneumonia	Present in about 25 p. ct.	Present in about 40 p. ct.	"	10 per ct	10 per ct.	Highest 108°, average 104 7°.
5. Interstitial chronic pneumonia of heart disease.	8 In middle life mostly	All males.	.....	Dec. to July, 100 per ct.	Both lungs always.	All of both lungs.	Hypertrophy of heart with or without endocarditis.	Cardiac disease.	Mos. or years.	Heart failure or uræmia mostly.	Cough, dyspnœa, and slight dulness.	Yellowish.	No change.	Present in about 28 p. ct.	Present in about 71 p. ct.	"	.....	.....	Occas'nally as high as 103°, gen. no rise temp

monia; 2, secondary lobar pneumonia; 3, embolic lobular pneumonia; 4, bronchial lobular pneumonia; and 5, the interstitial pneumonia of heart disease. These different divisions are, in my opinion, characterized by differences that are clinical as well as pathological, and I only follow in the steps of others when I ask for each variety a separate consideration.

Acute lobar pneumonia, as a peculiar form of lung inflammation, was, I think, first clearly differentiated by Grisolle, a student of Louis and Chomel (*Traite Pratique de la Pneumonie*, Paris, 1841). His studies were based upon 373 cases that fell under his personal observation, and it is but just to state that though much has been learned of pneumonia since the days of Grisolle, no work has surpassed his, in the completeness of its clinical and anatomical details; although his statistics lose value in some directions, because some of us, at the present day, have adopted a different classification for the less common varieties of pneumonia, which, in older times, were either grouped together under the general term "pneumonia," or were placed apart by themselves.

Acute lobar pneumonia occupies a unique position in the catalogue of diseases, for both anatomically and clinically it is unlike any known disease.

And we do well not only to distinguish it from secondary lobar pneumonia; from catarrhal or broncho-pneumonia, known sometimes as lobular pneumonia or capillary bronchitis; from septic pneumonia, known often as embolic or pyæmic, and from the interstitial pneumonia of heart disease, but also from pseudo-pneumonias, such as the so-called fibrous pneumonia (the fibrous phthisis of Sir Andrew Clark and others); from the catarrhal phthisis of Niemeyer (known as catarrhal pneumonia in some quarters); from syphilitic pneumonia (syphilitic phthisis), or any form of lung syphilis; from various other forms of interstitial pneumonia, such as are caused by the inhalation of foreign substances; and, finally, from hypostatic pneumonia, a bastard form, that is nothing more nor less than chronic pulmonary congestion. I should not forbear to mention that acute lobar pneumonia has also been called *croupous* pneumonia, from the fact that fibrin, which constitutes the chief characteristic of a croupous or membranous exudation, is of very frequent occurrence in the exudation that fills the vesicles: but I prefer the term lobar, because fibrin may occur to some extent in the exudation of lobular pneumonia, and because the word croupous has been largely used, chiefly in German literature, to contradistinguish any given exudation from the so-called diphtheritic, the differences being pathological, and not in any way clinical. In fact, the inutility of the term croupous is best shown by the fact that croupous and catarrhal processes may be combined in any examples of

pneumonia, whether lobar or lobular; and may also be associated with certain chronic processes, such as phthisis or syphilis. At any rate, it is often difficult in lobar pneumonia to determine whether fibrin is really present in the exudation.

Acute lobar pneumonia is the most common variety of pneumonia. In 100 fatal cases from my hospital and private records, I have found the several varieties represented as follows: acute lobar, 36 per cent.; secondary lobar, 19 per cent.; embolic lobular, 18 per cent.; bronchial lobular, 20 per cent.; interstitial of heart disease, 7 per cent. It is most common in males, and occurs most frequently between the ages of thirty and eighty.

And yet it may occur at all ages, but by common agreement broncho-pneumonia is the pneumonia of children; lobar, of middle life or old age; acute lobar, of middle life more particularly.

Acute lobar pneumonia is a disease that chiefly affects the residents of northern or middle latitudes. It is comparatively uncommon in equatorial regions.

According to the French observer Lombard, females were attacked twice as frequently as males; but Fagge, whose studies have been more recent and, I think, far more trustworthy, has found that it was chiefly a disease of the male sex. My statistics sustain those of Fagge, and even show that the ratio between males and females may be more than four to one.

When the disease originates in one lung, the right is usually selected, and this fact has been emphasized from the days of Andral to the present time, and abundantly sustained by thousands of post-mortems. And the same rule holds good, whether the disease be acute (primary) or secondary. When both lungs are attacked, the second lung is rarely involved until the affection in the first attacked has gained some headway.

In 33 of my cases the locality was as follows: In 17 the right lung alone was attacked; in 6, the left; in 10, both were affected. The disease usually commences in a lower lobe, and it has been agreed by those who have had the requisite experience, that this is the rule.

It has long been wondered why pneumonia chiefly affects the right side, and the question has arisen whether it is due to the common practice of lying by preference on the right side; to the increased functional activity of the right lung; or to its increased volume. It is difficult to answer the question. But, other things being equal, it is plainly to be seen that the increased volume of the right lung necessarily exposes a larger area to the causative agents of the disease.

The first stage is commonly called the stage of engorgement. The whole tissue increases in volume, and is infiltrated with a serous fluid, while there is more or less transudation of blood from the distended vessels. The second stage is called the stage of red hepatization. The lung is now of a deep red color, unyielding to the touch, and is difficult to distinguish from an inflamed liver. It contains no air, or very little, and almost no fluid. The cut surface has a rather rough or granular and dull aspect, as if some finely powdered substance had been strewn over the surface; each little speck corresponds to an air vesicle or cut bronchiole, which is filled with a little firm pellet, consisting of blood-cells and epithelium intermixed very frequently with fibrin, the latter holding the various elements firmly together. The red color of the lung at this stage is derived entirely from the red coloring matter of the blood corpuscles. In the third stage, that of gray hepatization, the diseased lung has assumed a different color. The reddish tint has yielded to a dirty gray, at first tinged with brown, and then with yellow. The tissue is now softer, and, on pressure, exudes a small amount of fluid, in color the same as the lung. The walls of the bloodvessels are also studded with leucocytes. In many cases dark pigmentation of the interlobular spaces is observed, the result in part of the congestion which the lung has experienced; in part, to other causes. The lung is now so greatly increased in size that it may weigh upward of sixty ounces. Normally, both lungs weigh about forty ounces.

Acute lobar pneumonia is very apt to begin with a chill of considerable severity, but it is soon characterized, more or less regularly, with pain in the side, cough, and difficult breathing. At the same time the patient experiences general malaise, pain in the limbs, and some headache. But, sometimes, instead of a regular chill, there may only be chilly sensations, with nausea and vomiting; or wandering pains may precede the chill. Within a few hours the temperature commonly rises to 103° or 104°. In both lobar and lobular pneumonia there is a peculiar alteration in the usual ratio between the pulse and respiration. According to my experience, the chronological order of events is as follows: 1, pain, prostration, and cough; 2, a severe chill; 3, nausea; 4, rise of temperature.

One of the most important early signs, though seldom the earliest, is fine crepitation, as it has been called. This peculiar phenomenon is heard only during inspiration, but it is not a sign that is positively essential; occasionally, it lasts the entire length of the disease. As soon as the second stage begins, there is dulness on percussion, with bronchial breathing and bronchophony. There is also increased vocal fremitus.

In the fourth stage, that of resolution, we hear the returning crepitant râle, the râle redux. Normal vesicular breathing will not return until the patient is thoroughly convalescent.

Let us review more closely the individual symptoms. In Grisolle's cases the chill occurred in 145 out of 182 instances, and then during the first twelve

hours of the malady. In 110 times it occurred at the very onset of the disease. Louis noted it in 61 out of 79 cases on the first day. According to these observers, the reason that the chill was not more frequently appreciated lay in the fact that it often occurred during sleep. Of course, other reasons suggest themselves, and one in particular is, that the patients may have mistaken the chill for the exposure to cold, which, in reality, existed only in their imagination. It is an important sign, and apt to be as pronounced as the chill of intermittent, puerperal, or yellow fever. It is not so prominent as the chill of pyæmia. A chill of this sort in old people, who are not specially prone to acute diseases, instantly raises the supposition of pneumonia. As already stated, my cases indicated that pain in the side usually preceded the chill. In 20 per cent. of Grisolle's cases the same phenomenon was noted. It is, therefore, of common occurrence.

Cough is also a very regular symptom. Grisolle found it in 89 per cent. of his cases, and during the first twelve hours of the attack. I am inclined to think that the locality of the affection, whether in an upper or lower lobe, does not influence the production of cough or affect its character. In old people the cough may be absent. In children it is almost always present. Sometimes it is the first symptom, but the cough may and usually does lessen as the disease progresses, even if it go on to a fatal termination.

The expectoration of pneumonia is peculiarly tenacious and variously colored. It is not always of the characteristic prune-juice color, though that is looked for; it may be red, black, green, or colorless. The characteristic sputum of pneumonia has three qualities: color, consistency, and coalescence. This sputum may occur on the first day, or not until the third or fourth; but the characteristic sputum, so far as the color is concerned, is not always present, and it may occur occasionally where no pneumonia is present, as in nasal or pharyngeal catarrh, where there has been hemorrhage; or a true pneumonic sputum may occasionally be seen in acute laryngitis, as I had the opportunity of observing very recently. In such cases the sputum may be quite coalescent, consistent, or may even be striated with a brownish coloration. We are told that in the time of Hippocrates a diagnosis of pneumonia was based on the character of the expectoration, but there are other signs more important than this one. In a certain class of cases the sputum is red or bloody in the first stage, but the color is usually that of iron rust; as the disease approaches its natural termination by resolution, the sputum is apt to be yellowish in color. In 2 of my cases there was no expectoration at all; in 15 it was either bloody, blackish, rusty, or greenish.

In 78 per cent. of the Grisolle cases he found that the pneumonic sputum occurred within the first four days, usually on the first day, but it might be delayed until the twelfth day. Often, however, groups of instances have been observed in which the sputum was uniformly colorless throughout the disease. Furthermore, cases have been seen by clinicians everywhere in which there was no expectoration at all; in very young children it is uniformly absent. Among other symptoms to be noted is a loss of appetite, that is generally marked. A certain degree of thirst is proportionate to the fever. Diarrhœa also is frequent, and nausea and vomiting occur in a goodly number of patients, as we shall see. The urine is often scanty, but there has been a difference of opinion as to the frequency of nephritic implication. Thus, while Grisolle says that albuminuria is common, and Rayer (*Traite des Malades des Reins*, vol. i. p. 578, Paris, 1859) sustained this view in a general way, they had not the experience that we have to-day. Albuminuria in acute lobar pneumonia is quite common, though not so common as in the interstitial pneumonia of heart disease. It is usually most marked at the height of the disease. Parkes (quoted by Sturges) was not far from the truth when he said that albuminuria might be present in 45 per cent. of the cases, though he appears to infer that sometimes it may not occur at all. It is unfortunate that urinary examinations are not made with more frequency or exactness in cases of pneumonia; for if this matter received due attention, I am convinced that a nephritic implication would be found more frequently than now appears from the published accounts of writers on this topic. Often we have to depend, as in my cases, upon hospital records; and since many of the patients are brought into the wards in a moribund condition, it is manifestly impossible to secure the complete evidence on this point that is needed for statistical purposes. But judging from analogous instances, we have a right to infer that the kidneys were affected in these imperfect cases as frequently as in others in which the histories were complete. Hence my statistics actually show a less amount of nephritic trouble than existed. They show, however, a percentage of 41: in 5 per cent. of this total there was chronic kidney disease of long standing; in 8 per cent. only did it positively appear that there was no urinary implication, as shown by clinical and post-mortem evidence. And therefore, finally, there was positive evidence of acute renal disease in 28 per cent. of the cases.

Now, though I am convinced that this percentage is really too low, I am equally well convinced that acute renal inflammation is not so common in pneumonia as I once thought it was. So far as the kidney is concerned, we have more to fear from the acute exacerbation of an old nephritis, where the damaged organ is suddenly called upon to do vicarious work, for which it has little capacity.

The importance of percussion was not known until 1763, when Avenbruegger's book appeared; but it remained for Laennec (*Traite de l'Auscultation*, vol. i. p. 27) to give a succinct account of the physical signs in pneumonia; and his discovery of the crepitant râle, as indicating the first stage of pneumonia, has proved to be a landmark up to and at the present time. In fact, but little has been added to our notions of the clinical aspects of pneumonia since the days of Laennec. The additions have been made by Andral, Chomel, Grisolle, Stokes, Williams, and last, but not least of all, Wilson Fox and Fagge.

In the first stage, that of engorgement, though we might expect to find dulness, we do not. But Grisolle found in this stage a loss of elasticity in the chest walls when the chest was being percussed, especially in the supra-spinous and infra-spinous fossæ. In lobular pneumonia it is generally admitted that there are no signs derived from percussion in this stage. In children whose chests are very sonorous, full resonance may be yielded. In the lobular pneumonia of children and central pneumonia there may be bronchial breathing without dulness.

The crepitant râle, according to Laennec and his followers, was thought to be the first pathognomic sign of pneumonia. But Stokes (*Diseases of the Chest*, Philada., 1844, p. 276) held, *per contra*, that puerile respiration preceded crepitation. Grisolle, in a measure, sustained the views of Stokes. The crepitant râle was first compared by Laennec to the noise made when salt was thrown on a coal fire. It has also been compared to the blowing up of a dry bladder; to the sound produced by pinching a piece of inflated pulmonary tissue held close to the ear; to the grinding of a lock of hair between the fingers or squeezing a little ball of tissue-paper near to the ear. This sound has met with various interpretations, but almost all observers are united in the opinion that it is produced by fluid matter passing into the vesicular substance of the lung. At some seasons the fine crepitant râle is rarely heard; in old people it may be replaced by a coarse crepitant râle. But Laennec (*Diseases of the Chest*, New York, 1830, p. 212) not only held, as I have already stated, that it was characteristic of lobar pneumonia, but that it occurred in no other affections except œdema of the lungs and pulmonary apoplexy. I think, however, that it is generally admitted now, in the best quarters, that fine crepitation is also heard not only in the several types of pneumonia but also in pulmonary phthisis and syphilis, or even in bronchitis, as Andral claimed. I might multiply instances from my individual experience to sustain this view, but I refrain from doing so, because I presume the point will be conceded by those who have made special studies in this direction.

Prolonged expiration, a symptom first noted by an American physician, James Jackson, of Boston (*A Memoir of James Jackson, of Boston*, 1855), is next to be considered. It precedes tubular or bronchial breathing, which sound has been compared to the breathing or blowing of air through a wooden tube. This latter symptom may not be recognized where there is liquid effusion. When the ear applied to the chest appears to locate the sound of the patient's voice nearer than in health, we have bronchophony. Where there is a considerable area of dulness the voice sounds may be metallic in quality. It appears singular that in pneumonia, even if one lung be extensively involved, there is rarely any alteration in the symmetry of the sides.

Pain is most frequent in the nipple; next, at the base of the lung. It also may be felt at any portion of the chest wall. The pain is due to pleurisy. It is not always present. The tongue is usually furred, but it may be dry or brown. It is affected in two-thirds of the cases. The pulse is usually 100 or more—it may reach 160; in children it often varies between 130 and 140. Jaundice is not very infrequent, and delirium is a common symptom, especially in subjects addicted to alcoholism. In my 55 cases of primary and secondary pneumonia, delirium was noted in 26 per cent. Coma occurred in 3 per cent. In many cases it is uræmic; in mine in 17 per cent. Coma, possibly delirium, may also be due to carbonization of the blood.

At first the respiration will rise to 22, perhaps 36 per minute, but within two days it may reach 40, 50, or 60; 64 is the highest I have known. In my cases the pulse-respiration ratio shows that there was uniformly a high ratio between respiration and pulse. Thus while the pulse was never more than the double of the normal, the respiration was often three times the normal, and in an average of 7 cases was about twice the normal. The highest recorded pulse I have known was 160; but the highest recorded respiration was 64; the lowest pulse-rate was 100; the lowest respiration-rate was 28.

The difficulty in respiration varies with the individual. Some may have a respiration of 40 and will not complain; others may feel embarrassed by a respiration of 24.

Inflammation of the lower lobes appears to produce more oppression than of the upper. In persons with contracted chests and abdominal distention the disease is not well borne.

A decided elevation of the temperature occurs in pneumonia. It may reach 103° or 104° within the first few hours of the disease. In children it reaches a greater height than in adults. The temperature rises from 1° to 2° at night and falls in the morning. The highest temperature in my cases was found to be 108°, and at death; the lowest 100.2°. In ten the highest average temperature was 104.3°.

The crisis usually occurs between the third and the eighth day; or, more accurately, between the

fifth and the seventh days. Acute lobar pneumonia is, therefore, of comparatively short duration. Unless it has unusual complications or sequelæ, the attack should not exceed fourteen days at the utmost. Any case that is claimed to have lasted more than two weeks should be regarded with the gravest suspicion. In 30 of my cases the duration was as follows:

In 1 . .	1 day.	In 4 . .	8 days.
In 1 . .	3 days.	In 4 . .	9 "
In 4 . .	5 "	In 3 . .	10 "
In 6 . .	6 "	In 2 . .	12 "
In 2 . .	7 "	In 3 . .	13 "

Of course, these figures of mine prove little except that the fatal issue, if it comes, may occur on any day of the disease, always within two weeks; but that the danger is greatest about the end of the first week, or, in reality, on the sixth day. This fatal epoch corresponds with the date at which the crisis occurs, according to most clinicians.

The immediate cause of death is usually heart failure, the tired heart muscle becoming exhausted as a direct result of the prolonged and exhaustive work it has had to perform; or indirectly through the influence of poisoned blood upon the nerve centres. In rare cases the respiratory nerves will yield, and respiration will stop, though the heart proceed. I have known it in two instances; one of which is not included in my tables.

My records show that in 17 cases, in which the direct cause of death was noted, the figures were as follows: in 11 heart failure, in 5 uræmia, in 1 respiratory failure.

There is usually no great difficulty in making a diagnosis in acute lobar pneumonia, but I have known it to be mistaken for empyema and abscess of the liver.

According to Sturges, pneumonia is produced by cold, dry, penetrating winds, while colder winds or variable winds with wet weather produce bronchitis (page 161). Grisolle thought that lobar pneumonia was not caused solely by cold, which, however, produced it occasionally. He thought that the chilly feeling described by patients at the commencement of the attack, and which they thought produced the pneumonia, was really the chill of the early stage, a point I have already alluded to. Of 200 cases collected by him, it was found that only 49 ascribed pneumonia to catching cold. Barthez (*Leçons de clin. Méd. Sestier.*) found the proportion 38 out of 125; Chomel (*loc. cit.*), 14 out of 79; Bouillaud, 16 out of 26. Grissolle thought that where cold produced pneumonia it was not due to a sudden and short exposure to an extreme change of cold air; but to a prolonged exposure to a less degree of cold, as to a current of cool air. Laennec thought that pneumonia was due to cold, long continued, or received when the body was heated or perspiring. Epidemic pneumonia might be due to an absorption of deleterious substances. Laroche, in an elaborate work on *Pneumonia in its Relation to Autumnal Fevers*, published in 1854, disposed of the view once held that pneumonia had a causal connection with autumnal fevers, and ascribed its origin to atmospheric causes, exposure to cold, violent exercise of the voice, inhalation of irritating vapors, wounds of the chest, metastases in gout, rheumatism, and skin diseases, and to surgical operations.

I am inclined to think, however, that we agree in the main with Grisolle, Bretonneau, and Frank (*Méd. Pratique*, t. i. p. 164) that the inhalation of irritating gases or vapors does not produce lobar pneumonia, but the lobular variety.

Some later writers, like Ziemssen, have thought exposure to cold a very infrequent cause of pneumonia; he traced it in only 10 out of 186 cases; Griesinger in only 4 out of 212. I found it ascribed in 22 per cent. of my cases.

But if we note the time of the year at which pneumonia is prevalent, we at once realize that it is a disease of the late autumn, winter, and spring months. Thus, in my 36 cases, 27 fell between October 1st and June 1st; 9 only in the remaining four months.

Figures apparently show that the occupation has little bearing on the causation of acute lobar pneumonia, and singular as it may appear at first sight, the ratio of disease among those who have led an indoor life to those who were engaged in out-of-door pursuits was as 11 to 10 in my tables. But we should not misconstrue these figures, for various reasons, one of which is, that, in reality, the former class is often more exposed to sudden atmospheric changes than the latter class. And so it happens that the disease is common among firemen, cooks, blacksmiths, waiters, and laundrymen, largely because their occupation, though indoors, necessitates great physical activity in an atmosphere that is alternately hot and cold. On the other hand, others who work indoors, like clerks, telegraph operators, and barbers, are apt to be exposed to drafts, or degrees of temperature which they cannot control.

From the foregoing, it is made to appear that there may be two varieties, at least, of acute lobar pneumonia: First, a sort of epidemic form, sometimes associated with diarrhœa or dysentery, where persons have been crowded together and compelled to inhale foul air. Such forms of pneumonia may be called pythogenic; and under this head it would be proper to class such epidemics as Dr. Darlington has described. Secondly, a pneumonia due directly to cold, such as was described by the Icelandic physician, and which is universally recognized, though it is rarely seen in the epidemic form that he describes. There are, doubtless, other causes which we have yet to discover.

I should not fail to notice here that the infective

character of acute lobar pneumonia has been sustained in a measure by the researches of Griffini and Cambria, who, in 1882, described peculiar bacteria in the sputum of patients suffering from lobar pneumonia. Numerous other observers have detailed somewhat similar experiences; and in the following year Friedländer found spherical microörganisms which were described as oval and contained within a distinct capsule; but in 1884 similar bodies were found in catarrhal pneumonia, which is generally held to be a disease of dissimilar character; and in 1885 Sternberg described somewhat similar capsulated bodies in the saliva (*American Journal of the Medical Sciences*, July, 1885); but, briefly stated, it appears that no observer has as yet complied with Koch's law as to the determination of whether or not a given microcyte is the cause of the disease, viz.: by, first, its successful culture apart from the body; second, its successful inoculation on the body with the subsequent production of a pathological condition the counterpart of the disease in a given organ. Thus it would be necessary to show that a pure culture inoculated upon the blood remote from the lungs produced lobar pneumonia. Experiments, however, have almost always failed in this respect, and it has been found necessary to inoculate the lung tissue, where any foreign substance will, if injected, produce pneumonia. Even in such experiments it is *lobular*, not *lobar*, pneumonia that has commonly resulted.

Pleurisy is a complication that is to be expected, and the ancients were right when they spoke of lobar pneumonia as pleuro-pneumonia. The pleuræ are always involved when inflammation reaches the surface of the lungs. So that pleurisy is never absent, except in such rare cases as when the disease is central. But such acute observers as Stokes have questioned this now-established fact.

A comparatively frequent complication is pericarditis, which develops either by an extension of the diseased process or by a simultaneous implication. A more important complication is disease of the kidneys. In a large number of the cases, as we have seen, if not in one-half, the kidneys are involved; there is then more or less swelling of the parenchyma of the organ. The spleen is apt to be enlarged also; and there is catarrh of the intestinal tract. Pericarditis occurs in about one-third of the cases according to Sturges; in my cases, in ten per cent.

Laennec thought that abscess of the lung was a very rare termination of pneumonia. In an experience lasting twenty years, he found it only five or six times; Chomel only twice; Andral and Louis only once each. Grisolle saw one case in ten years' practice, and Grisolle found that the united testimony of Russians, Poles, Swedes, and Finns was to the same effect. An abscess is described as containing laudable pus, which is inodorous, and is found in the centre of hepatized tissue. The line should be sharply drawn between such an abscess and gangrene of the lung, or cavities in tuberculous or syphilitic subjects, or in the metastatic deposits of pyæmia, or in septic endocarditis. In my thirty-six cases of acute pneumonia it never occurred; but gangrene was noted in one instance. According to my notions, phthisis can never develop from lobar pneumonia; but the discussion of this matter is out of place here. As to the so-called cirrhosis of the lung as a sequel of pneumonia, on which authors seem to be divided in opinion, I have nothing to say, because I have no experience in the matter.

The important question of the mortality of pneumonia which so agitates and interests the medical profession to day scarcely comes within the scope of my paper; but I cannot let it pass unnoticed, if only I indicate some of the sources of previous error and make suggestions by which we may reach conclusions that have at least an approximative value. For it is profitless to give statistics of a general disease like pneumonia unless we know: (1) the variety; (2) the decade of the patient's life; (3) the general character of the attack. For lobar pneumonia has quite a different mortality rate from either variety of embolic pneumonia, the cardiac, or pyæmic. So the rate is different in childhood, in adult life, and in old age. And the fatality at some seasons appears to be greater than at others, under the same general form of treatment.

But though I have no trustworthy statistics to offer I will mention some that have come down to us, and they can be accepted for what they are worth. According to Sturges, the mortality among the most eminent of the old French school was as follows; Louis, 30.8 per cent.; Andral, 55.4 per cent.; Chomel, 32 per cent.; Bouillaud, 11 or 12 per cent.; Grisolle, 16 per cent. Bouillaud had revived the practice of bleeding which was prevalent in Europe during the last century, especially in Italy, where it was not uncommon to take from the unfortunate patient as much as ten pounds of blood during an attack. It was said that the mortality by this method of bleeding, together with the use of tartar emetic, was reduced to 10 per cent. It was claimed also that hepatization of the lung was prevented. Bouillaud was satisfied with five pounds of blood.

Just before the middle of this century, however, Skoda published some statistics that tended to prove that pneumonia was a self-limited disease. But the figures given about the year 1842, by Fleischmann, a homœopathist, showing a mortality of less than 6 per cent., made a great impression on medical minds, and whether correct or not, led Dietl, a non-homœopathic practitioner, to try the dietetic method. The result was, in the first series of cases, a mortality of

only 7.4 per cent. But the most astonishing results were soon published by Barthez: of 212 cases between the ages of two and fifteen years, only 2 died, a mortality of less than 1 per cent. Here we note, for the first time, an important fact, viz., that the fatality from lobar pneumonia in children is very small. Then Bennett, by his so-called restorative treatment, saved 4 out of 125, or 3.2 per cent. His plan was to give salines to obviate the "viscosity" of the blood; wine to sustain the system; and colchicum and nitrous ether to "favor the excretion of urates." The best results, however, appear to have been given by Zeigelé, who lost none in 40 cases. The patients, however, were young.

It is apparent, after a brief study of these, or of any similar statistics, that their variation is to some extent a natural one. And though it is ostensibly true, in my individual judgment, that the expectant plan is the most successful on the whole, still the results are by no means uniform in the hands of the same person. This is partly due to reasons already given, viz., that there is much variation in the types of pneumonia from year to year; and that the pneumonia of childhood, adult, and old age are different in their expectation of life—in fact, that each case of acute lobar pneumonia stands apart by itself.

Thus the late Bamberger, of Vienna, during an experience of three years, had a mortality of 11.2 per cent.; during another three years of 18.19 per cent.

In the year 1858 the mortality at St. Thomas's Hospital was 17 per cent.; in 1859 it was 5.7 per cent. And I have been unable to learn that the variation in results was due in any way to differences in treatment. At the present day we are more than ever likely to misconstrue statistics, unless we have the most positive information as to the variety of pneumonia which we have under consideration, because the term "pneumonia," under one or other of the forms already enumerated, enters much more frequently into post-mortem records than formerly.

But as I have already stated, acute lobar pneumonia is different from secondary lobar pneumonia, catarrhal from embolic, and each from the interstitial of heart disease. I hold them to be true types of pneumonia, but, as I intend to show on another occasion, they are totally distinct in etiology, course, and termination. One of the best foreign writers on this subject has fallen into the most obvious error of taking his statistics from all of these varieties combined.

Admitting, however, that these statistics are of value, we have evidence, as I have said, that the so-called expectant plan is the best. I believe that we have passed the period when any one will attempt to prove that we can arrest the disease. We do, indeed, sometimes meet with cases of pulmonary congestion, in association with cardiac or renal disease or malaria, that present some of the signs of lobar pneumonia, but the prompt relief by stimulants or anti-periodics teaches us the nature of the congestion.

The cause of death also demonstrates the obvious direction in which our main efforts are to be made. It is not so much in the direction of reducing the temperature as toward sustaining the heart; next, to obviating renal complications. Hence, our clinical data supplemented by our pathological *do* point out the line of treatment. I doubt whether the high temperature in pneumonia is in itself a demon that we must attack and overthrow; and I have been led to believe, by post-mortem studies, that the use of antipyretics to reduce temperatures not only weakens the heart's action, but has some unfavorable action on the kidneys. It seems to me that since the introduction of the newer antipyretics, especially where they have been employed in large doses, the renal implications have been greater than before. I believe that every case of acute lobar pneumonia should be treated by itself, and the indications should be met as they arise.

Hence, the remedial agencies that have, from time to time, met with favor have an appropriate field for their employment. I have often seen benefit from copious and repeated cuppings in sthenic cases. In less vigorous persons I have seen relief follow upon the cold-water applications. In cases of defective hepatic action, I have seen relief from mercurials in large doses. In persons with weak hearts I have seen the patient carried safely through with alcoholic stimulants. In renal complications I have seen marked relief to the pulmonary symptoms from remedies chiefly addressed to the kidneys. Reduction of the temperature is indeed a relief to the patient, but I fancy it is safer to accomplish it through the aid of the simpler remedies that cause diaphoresis, rather than by those that act *more* promptly, but whose secondary effects are, to state it mildly, of doubtful value. I think we now realize that though high temperature in acute pneumonia is a symptom that is alarming, it is rather because it is an index of violent systemic disturbance than because of the bodily heat itself; since the patient may successfully endure a much higher degree of heat than obtains in pneumonia, and yet survive.

II. Secondary Lobar Pneumonia.

There is a positive advantage in retaining this division of lobar pneumonia, which, as I have stated, was recognized by the old French school, while it has also been approved by prominent clinicians up to the present day. In the nineteen cases from my post-mortem records, from which I have drawn my conclusions, there is seen to be a line of phenomena which plainly indicate certain differences between the primary or acute, and the secondary form.

These bear: 1, upon the age of the individual;

2, the nature of the antecedent or concurrent affection; 3, the apparent causation; 4, the character of the pulse and respiration; 5, the tendency to secondary suppurative changes in the lung; and, lastly, 6, the temperature.

In secondary pneumonia the ordinary clinical signs are either masked by the concurrent disease, or are so ill-defined, that the pulmonary attack may pass unnoticed, even when the physician is observing the case with ordinary vigilance; and so it happens that sometimes in our best hospitals, secondary lobar pneumonia may first be detected at the post-mortem examination. I feel confident that my colleagues, in pathological research, will bear me out in this statement. Indeed, the attention of the physician may not be directed to the pulmonary complication, because the patient himself has not had his own attention directed to it. Such things happen with old people; or it may be that a physical examination of the chest is impracticable, and then the physician is fully exculpated, if the other ordinary physical signs are absent.

I have observed the following antecedent conditions in secondary pneumonia, and I enumerate them as I have found them, without committing myself to an opinion as to their etiological value: nephritis in 5, alcoholism in 2, phthisis in 2, burns in 2, rheumatism in 1, fracture of the ribs in 1, hypertrophy of the heart in 1, pleurisy with effusion in 1, pericardial effusion in 1. Secondary lobar pneumonia I have found in contemporaneous connection with the following affections: Abdominal dropsy in 1, pericardial effusion in 1, gangrene of the extremities in 1, aneurism of the aorta in 1, bronchitis in 2, syphilis in 2, endocarditis in 2, hydrothorax in 1. And I enumerate these concurrent affections also just as they appear upon my records as typical cases of secondary lobar pneumonia. In particular, I would say that neither phthisical nor syphilitic processes had any apparent connection with the pneumonia. In fact, all cases in which there was any suspicion of phthisis or syphilis as possible causes of lobar pneumonia were thrown out of the computation.

But I may at this point state that, though the term secondary pneumonia has been in constant use for more than half a century, it is not profitable to use the statistics bearing on this matter, as they have been furnished to us. Without going into wearisome particulars, it should suffice us to know that it was confounded with acute lobar pneumonia by Grisolle, and with hypostatic pneumonia (venous congestion) by Louis. Secondary lobar has been held to occur chiefly between the fourth, fifth, and sixth decades of life. I have found it chiefly between forty-five and eighty.

In regard to sex, though it has been held that males and females are equally prone, my tables show that the males preponderate in the proportion of 17 to 2.

It seems to be most common in winter, and of my 19 cases not one occurred between May 1st and October 1st, though I cannot see that this rule should always obtain, because if, as would appear, the bursting of an aneurism, a surgical operation, etc., or other constitutional disturbances were exciting causes, we have no right to expect that the season of the year should have any special influence.

As I have already intimated, secondary lobar pneumonia is usually insidious; the chill is frequently absent. It probably does not occur in one-fourth of the cases, and then has little intensity. The pain in the side may also be absent. The difficulty in breathing may not be marked. The crepitant râle will, however, be heard, as a rule. The temperature will rise rapidly, as in acute pneumonia, but it will average somewhat lower, though the temperature may not indicate the severity of the attack; with a comparatively high temperature the patient may survive; with a comparatively low temperature he may succumb. The average temperature will be about a degree lower than in acute lobar pneumonia. I have found it to average at the highest 103.6°. The pulse will often rise sharply at the outset, and may reach 140; but it will average about 120 to 124, a lower rate than in acute pneumonia. Bronchial breathing and dulness may be the most decided symptoms, and they are the most common in my experience. They were noted, in fact, in about 70 per cent.

The expectoration is apt to be scanty and often affords us little help in the diagnosis. I have noted it only in about one-third of my cases, when it was either bloody, rusty, or black.

Renal symptoms are apt to be more prominent, however, than in acute pneumonia.

As indicating the difference in the type of this variety of pneumonia, there is found a more decided tendency to suppuration than in the acute form.

The duration of secondary pneumonia proper is about the same as in acute pneumonia; but the crisis is apt to come earlier, because the patient is already exhausted by the antecedent trouble. Hence, I find that out of 14 cases 8 died within forty-eight hours, and that the period of greatest danger was between the second and third day.

The immediate causes of death are attributable mainly to the same three conditions that are prominent in acute lobar pneumonia, viz.: 1st. Heart failure, and in about half the cases; 2d. Uræmia; and last and least, respiratory failure from the toxic influence of the unhealthy blood on the nerve centres.

These facts, in my estimation, sufficiently indicate the proper line of treatment.

17 EAST FORTY-FOURTH ST.

NOTES ON THE TREATMENT OF INFLAMMATION OF THE FRONTAL SINUSES.

BY RALPH W. SEISS, M.D.,
ADJUNCT PROFESSOR OF OTOLOGY IN THE PHILADELPHIA POLYCLINIC.

JUDGING from a perusal of the recent literature upon this subject, the treatment of inflammation of the frontal sinuses is most imperfectly understood by the general surgeon, and notes on improved methods of technique with their results seem timely.

As tersely described by Bosworth, "the frontal sinuses are two irregular cavities which lie between the two tables of the frontal bone. They are absent in children, but become developed in adult life. They communicate with the nares by the infundibulum, a rounded canal which opens into the middle meatus." They are lined with a vascular mucous membrane covered with ciliated epithelium, which is continuous with that of the nasal cavities.

Unless due to external violence or to the presence of neoplasms or foreign materials in their lumen, inflammation of the brow sinuses is always dependent on intra-nasal disease. Leaving the former rare causative factors—which will be found described in the classical text-books on rhinology—we find that almost every stage and variety of rhinitis presents a corresponding condition in the frontal sinuses.

In all severe cases of acute coryza the infundibulum is more or less occluded by swelling, and there is hyperæmia of the lining mucous membrane of the frontal cavities, as is clearly shown by the marked brow pain and the sense of distention in the supra-orbital region. It is in aggravated cases of this disease that true inflammation of the frontal sinuses is found; a patient suffering from a severe acute coryza "takes fresh cold," and as a result the nasal inflammation is greatly increased, and the patient soon complains of great pain in the region of one or both frontal cavities, which is soon followed by external tumefaction, the face often being curiously distorted by the swelling, and the upper eyelid œdematous. Reeve, of Toronto, has published in the *Canadian Practitioner* some cuts which give an admirable idea of the deformity in this affection.

Constitutional symptoms, consisting of pyrexia and often great nervous disturbance, now appear, and the patient is often forced to confine himself to bed. Somewhat later in the course of favorable examples there is a marked muco-purulent or sanious discharge from the nasal passage of the affected side. In the worst type of cases a true abscess forms, which may penetrate the anterior wall of the sinus or, in syphilitic subjects especially or, perhaps, exclusively, the abscess may perforate into the cavity of the cranium.

The symptoms in such cases are of the gravest character: delirium, coma, and paralysis ending in death, if not relieved by operation, are usual, or the patient may make an imperfect recovery delayed by many complications. Examples of this grade of severity are, however, exceedingly rare, and may nearly always be prevented by proper treatment during the earlier stages. Permanent dilatation of the frontal sinus may result from repeated attacks of purulent inflammation, causing much facial deformity.

In all cases of chronic rhinitis, especially of the advanced and sclerotic type, there is interference with nasal drainage and partial stenosis of the infundibulum, with the resulting symptoms of persistent frontal headache, and a sense of tension in the supra-orbital regions — the excessively common "catarrhal headache;" a form of suffering which often causes patients to apply for relief. Subjects who have inherited or acquired the "catarrhal tendency"—extreme liability to "take cold" from the slightest exposure, resulting in all the symptoms of acute coryza, but lasting for a few hours only, or a day or two at most—frequently suffer greatly from brow pain, often of considerable severity and repeated at frequent intervals, from acute hyperæmia of the frontal sinuses which they not infrequently regard as the most serious symptom of their disease.

Lastly, in some cases of chronic nasal inflammation, especially of the true atrophic type, there is an actual chronic purulent inflammation of the frontal sinuses, pus being discharged through the nasal cavities—this condition is, however, not common.

The treatment of hyperæmia of the brow sinus occurring in the course of an ordinary acute coryza is, fortunately for the patient, very satisfactory. The first indication is to reduce intra-nasal congestion, and thus relieve stenosis of the infundibulum. In the muriate of cocaine we have an agent perfectly suited to meet this indication: a small pledget of cotton soaked with not above ten drops of a five per cent. solution, is to be tucked up over the anterior portion of the lower turbinated body by means of a very delicate ear forceps (of course, under perfect inspection), and allowed to remain for about five minutes. The result is nearly always immediate, and frequently permanent relief from the tissue contraction; the pledget being removed, the intra-nasal region should be gently sprayed clean with some mildly stimulating, but entirely unirritating, antiseptic formulæ; the following is a favorite with the writer:

℞.—Listerine (Lambert) . . . . . f℥iv.
Acid. boric. . . . . gr. xx.
Aq. rosæ } . . . . . āā f℥ij.—M.
Aq. dest. }
S.—Use in atomizer.

The Schneiderian membrane being carefully cleared of all adherent mucus and dislodged epithelial elements, a powder somewhat like the follow-

ing should be insufflated into the region of the infundibulum:

R.—Morphinæ sulph.	gr. vj.
Atropinæ sulph.	gr. j.
Bismuth. subcarb.	ʒijss.
Acaciæ pulv.	ʒjss.—M.

This formula must be carefully *bolted* into an impalpable powder. From two to four grains are to be used at each insufflation in the case of adults, much less when used in the case of children; four grains representing a full therapeutic dose of atropine.

In mild cases frequently no further treatment will be called for, or if somewhat severe in character, one or more daily repetitions will cure the case. Attention to the condition of the digestive tract is, of course, always called for, and a mild cathartic may be given. The bromides of potassium and sodium given in large doses, three to four drachms in the first twenty-four hours, and two drachms *per diem* subsequently, have often had an admirable effect on this condition in my hands.

Where deformity is evident and the pain great, more energetic measures will be called for. In addition to the intra-nasal applications I invariably order atropine sulphate internally, $\frac{1}{480}$th of a grain, every hour for sixteen hours, or until the throat is very dry. If there is decided tumefaction in the region of the sinus externally, a blister of cantharidal collodion should be placed over the frontal sinus or just above it. The symptoms may be expected to abate in twenty-four hours under this treatment, especially if the patient can be confined to the house. Without treatment even the mildest class of cases are exceedingly apt to go on to suppuration, the duration of pain and deformity occasionally being from two to three weeks.

The treatment of pus accumulations in the frontal sinuses has heretofore been usually of a severely heroic character, consisting of opening the anterior wall with a trephine, and frequently in addition passing a rubber drain through the external cut and through a counter-opening into the nose. In several works on diseases of the nose, which are regarded as classics, the writers speak, as a matter of course, of opening the brow sinuses through the nares, but none, so far as I am aware, gives any detailed account of methods nor reports any cases. The operation is regarded by the writer as one of extreme difficulty and much danger; trephining the anterior plate, at least, as a preliminary step is much to be preferred.

Lately Jurasz has reported several cases in which he was able to introduce a fine metal probe into the frontal sinuses through the infundibulum, thus opening a drainage canal for the catarrhal or purulent products to escape.

Trephining is, in my opinion, called for with extreme rarity in this affection; the resulting cicatricial deformity is great, and the dangers of sepsis largely increased; marked constitutional or cerebral symptoms can only justify its performance. If decided on, it must be done under the most rigid antiseptic precautions. Opening the infundibulum by even the most skilful manipulation of any probe, seems to the writer a most unscientific and dangerous procedure; any surgeon familiar with the intra-nasal region knows how exceedingly ill the Schneiderian mucous membrane endures mechanical irritation, and attempted dilatation of the infundibulum, even when possible, seems more likely to produce additional inflammation and stenosis of the canal than to give exit to pus. If the above method of procedure is consistently carried out, even pus accumulations will be discharged through the infundibulum, and a cure without operation or deformity result.

As above mentioned, many cases of chronic rhinitis, especially those in which the catarrhal tendency is particularly marked, suffer from severe congestion of the frontal sinuses with brow pain and much local discomfort. Very frequently these "catarrhal headaches" can be permanently relieved by proper treatment of the naso-pharynx without special attention being directed to the inflamed sinuses. If drainage from the infundibulum is interfered with by either vascular or fibrous intra-nasal swellings, they should be "tacked down" by Bosworth's method, and the planes of drainage brought into a normal condition, when a cure will result.

The following slight modification of Bosworth's technique is used by the writer in binding down hypertrophies for this and other purposes. A small cotton tuft saturated, but not dripping, with a five per cent. solution of cocaine muriate is placed in contact with the area to be operated upon, and allowed to remain for from four to eight minutes; tight contraction of the tissues is the result. A recently made, fully saturated solution of chemically pure chromic acid is then to be used in the following manner: a light, steel cotton-carrier, such as is used in ear work, is to be tightly bound at its extremity with a tuft of cotton, which when wound on the probe must not be above two millimetres in diameter, or more than one centimetre long. This pad being saturated with the acid, and carefully mopped with dry cotton until dripping is impossible, is to be carried, under full inspection, to the point of greatest hypertrophy (decided upon *before* the cocaine was applied), and held firmly in contact with the mucous membrane for at least twenty seconds.

Great condensation of the turbinated tissue at the point of contact results, together with a slough of varying, but always shallow, depth; the ultimate and speedy effect being to bind down firmly and

permanently the offending mass of tissue. A strong solution of bicarbonate of sodium should always be at hand, and if the acid show any tendency to spread, it must be liberally mopped over the seat of the eschar. Two or three "tackings" will nearly always assure good infundibular drainage, and along with general intra-nasal applications and bromides internally will, in almost all cases, rapidly cure the frontal headache.

The "catarrhal tendency" calls for treatment by regulated bathing, scientifically directed open-air exercise, proper clothing, and the administration of strychnine sulphate in progressive doses; the *gouty diathesis* will be found with extreme frequency in this condition, and advanced *neurasthenia* is frequently causative of the "catarrhal tendency," and will call for appropriate therapeutic measures. Leaving the complicated relationship for future consideration, it has been my experience that a very aggravated catarrhal diathesis is very frequently associated with *irritable heart*, a "cardiac explosion" almost always following or preceding a "cold."

Chronic purulent inflammation of one or both frontal cavities is certainly an exceedingly rare disease in the neighborhood of Philadelphia, and vague accounts of its occurrence and complicating influence in "nasal catarrh" must be taken *cum grano salis*. The symptoms complained of by probable cases of this disease are those already detailed in an aggravated form.

The prognosis is generally very unfavorable owing to the intractable nature of the causative nasal disease.

As to treatment, it may be confidently stated that if the nasal inflammation can be controlled and the infundibulum kept patulous, the frontal symptoms will cease. In a case of advanced atrophic rhinitis with the usual pharyngeal, laryngeal, and bronchial complications, now under treatment by the writer, in which a certain amount of purulent inflammation of both brow sinuses certainly existed, complete relief was gained by the repeated use of the faradic current; the positive pole being placed well up in the naris in the region of the infundibulum, and the negative over the brow of the corresponding side; careful and long-continued treatment of the *rhinitis cirrhotica* being, of course, persisted in, the methods followed having already been described by me in THE MEDICAL NEWS. Blisters over the frontal cavities have also yielded good results in my hands in these cases; and bromides, iodides, and ammonium chloride are valuable in selected cases.

In conclusion, it cannot be too emphatically stated that all the inflammatory diseases of the frontal sinuses, above noted, are wholly dependent on intra-nasal conditions, and the good results of treatment will be in direct proportion to the success obtained by nasal therapeutic measures.

49 NORTH SEVENTEENTH STREET,
PHILADELPHIA.

CASE OF ABSCESS OF LIVER; ASPIRATION; DEATH.

BY HENRY M. FISHER, M.D.,
PHYSICIAN TO THE EPISCOPAL HOSPITAL, PHILADELPHIA.

WILLIAM D., aged thirty-seven, married, English, cloth-finisher, was admitted to the Episcopal Hospital, November 6, 1888.

Patient stated that his health had always been good, but that eight weeks before his present admission to the hospital he began to have pains in his legs, back, and chest. Two or three weeks later, in consequence of the abdominal pains and obstinate constipation from which he suffered, he applied for admission to the Episcopal Hospital. Under treatment his pains diminished, however, and he left the hospital after a fortnight's treatment, but soon returned in consequence of an aggravation of the pains, and was first seen by me about three days after his readmission.

He had had no vomiting and no anorexia. Three weeks before his readmission he had noticed a swelling of his legs and abdomen and that his skin had a yellowish tinge.

Upon admission he had marked jaundice and there was œdema of the lower extremities, and apparently slight ascites. Liver dulness extended in the mammary line from the fourth interspace six inches, and the lower edge of the organ was distinctly felt in the median line three inches above the umbilicus. Abdominal veins were prominent and much tympanitic distention of the intestine. There was well-marked bulging in the right hypochondrium, and over the area, where the bulging was, marked pressure caused pain, while pressure over other portions of the abdomen did not appear to cause much discomfort. Bowels very much constipated. Ordered a muriatic acid mixture.

November 14. Increased bulging and fluctuation being discovered, Dr. Hopkins aspirated with a capillary trocar about two inches below the costal margin in the right hypochondrium and drew off five ounces of blood-stained pus. Five hours later, patient had a large chalky movement of bowels.

Ordered aromatic sulphuric acid, gtt. xv t. d., and quinine grs. xvj daily.

15th. Dr. Hopkins drew off with the aspirator eighty-four ounces of blood-stained pus. The aspirator canula was allowed to remain in the wound and the cavity was ordered to be washed out twice daily with Thiersch's solution. After the operation a great deal of clear bile and blood-stained pus drained away.

16th. Patient began to cough last night, and this morning has marked dyspnœa. Respiration 40. Marked dulness on percussion over lower third of right chest, with tubular breathing. Impaired resonance over lower fourth of left chest also, and breathing over this area somewhat bronchial in

character. Free discharge of bilious, grumous pus from the wound. Ordered carbonate of ammonium grs. x every two hours, and whiskey, twelve ounces daily.

22d. Impairment of resonance over lower third of right chest continues, and some subcrepitant râles are heard at the junction of the middle and lower third of the right chest. Dyspnœa has diminished, but patient is weaker and greatly emaciated. Has been taking for three days fel bovis, grs. x, extract. pancreatis, grs. v, ter in die. To-day ordered in place of carbonate the muriate of ammonium, grs. xx t. d. Passages clay-colored, and patient has a dusky hue.

The drainage tube having come away Dr. Hopkins replaced it by a larger rubber tube, and found that a sound passed easily five and a half inches into the abscess cavity. In spite of this, drainage is not satisfactory, as in injecting the cavity only a little grumous discharge is brought away. Appetite not markedly impaired.

From this time patient became progressively weaker. Large amounts of bloody and bilious pus and almost pure bile drained away.

On the morning of the 28th he was unconscious; he died in the afternoon of this day, just two weeks after the first puncture of the liver had been made.

Post-mortem examination, thirty hours after death. Body extremely emaciated. Decomposition had already begun.

Heart. Tissue friable, valves competent. Both auriculo-ventricular valves contain chicken-fat clots.

Lungs. Both lungs very much congested; right intensely so at its lower half, and shows very numerous hemorrhagic infarctions, but there is no pneumonic consolidation. Lobes of right lung glued together by recent adhesions. Right diaphragmatic pleura very much thickened by the deposit of lymph.

Peritoneal cavity contains a considerable quantity of blood-stained serum. Transverse colon glued to omentum by adhesions, and the lower end of the spleen is also adherent to the colon. Mucous membrane of large and small intestine throughout congested, and near the ileo-cæcal valve the colon shows very intense injection, and mucous membrane appears eroded in places, but no well-marked ulcerations are anywhere seen.

Liver extends from fourth interspace in the mammary line, to a point two and a half inches below the costal margin. Its tissue is stained with bile and is friable. There is a well-marked concave depression of its anterior surface. Upon section, a considerable amount (perhaps one pint) of grumous, blood-stained pus is evacuated, and it is then found that the tissue of both lobes has been largely undermined by an enormous abscess, fully one-third of the substance of the organ having been eroded in the ulcerative process. The abscess cavity is about five inches in length from above downward, extending from a point two inches from the upper margin of the liver to a point about one inch from its lower margin, and is about eight inches in its transverse diameter. A bridge of tissue, about half an inch in thickness bounds the abscess anteriorly. The abscess cavity contains numerous shreds of false membrane, but no marked evidences of commencing cicatrization are anywhere seen. *Gall-bladder* empty; its mucous membrane shows inflammatory thickening, and the cystic duct communicates directly with the abscess cavity. In separating the liver from its adhesions to the duodenum, the common gall-duct was unfortunately cut away, and its exact relations to the abscess could not be determined. Apparently it had been completely occluded by bands of organized lymph.

This case does not, it is true, throw any new light on the causation of hepatic abscess in general. There are, however, abundant grounds for considering all cases of hepatic abscess to be the result of septic infections. The only difference, as it seems to me, between the *pyæmic* and the *tropical* abscess of the liver so called is, that in the first the septic material expends its energies upon the liver as well as upon other organs, whereas in the tropical abscess the liver alone may be involved. In the case I have just reported, the liver, a portion of the right lung, and the adjacent portions of the peritoneum and pleura were involved. And the starting-point of all such suppurative inflammation in the liver, except in those rare cases in which the abscess is the result of direct violence, is undoubtedly either the intestine or gall-bladder.

Of course, where the mucous membrane of the intestine is actually ulcerated, as in typhoid fever and dysentery, poisonous germs might be supposed to gain freer access to the portal circulation than where it is either intact or simply eroded.

That such poisonous germs do actually exist in the intestine, not only in cases of acute febrile disease but also in cases of chronic enteritis and entero-colitis, has been proved. Now, in the case reported, there were evidences of chronic entero-colitis in the thickening and roughening of the mucous membrane of the whole intestinal tract. When constipation accompanies intestinal catarrh, as it appears to have done in this case, the danger of absorption of septic germs would necessarily be very greatly increased. The danger would, of course, be still further increased by privation, the eating of badly cooked, indigestible food, and, above all, by the drinking of impure water.

That tropical heat is not always and necessarily a factor in the production of the so-called "tropical" abscess, is shown by the fact that the disease appeared to have developed during the prevalence of cool autumn weather; and only so far as a high temperature favors the propagation of many poisonous germs can it, I believe, be considered to hold a causative relation to abscess of the liver.

As Dr. Osler has recently pointed out, we must dismiss from our minds the impression that abscess of the liver, the "tropical abscess" of the books, is, in our climate, a rare disease. The case reported is

the third that has been treated at the Episcopal Hospital in the last three months. The fact of their occurring soon after a severe epidemic of typhoid fever in a section of the city imperfectly provided with sewers, and which draws its main water supply from a notoriously impure source, certainly strengthens very much the theory of a septic causation.

With regard to operative interference in such cases, my experience is in accord with that of others, that mere aspiration is useful only as far as it tends to prevent the bursting of the abscess into some important cavity, like that of the peritoneum, when the result of such bursting would almost necessarily be quickly fatal.

Of course, if the existence of a small abscess in the liver can only be determined early, thorough evacuation might be made with the aspirator, but *small* collections of pus rarely are, and, probably, rarely can be determined with accuracy, unless they happen to be close to the surface of the organ, unless the exploring needle is used. The use of the exploring needle in a doubtful case would seem to be perfectly justifiable.

But where the abscess is of considerable size, free incision would seem to offer the only hope of free drainage and subsequent cicatrization. Where adhesions have not already been formed sufficient in extent to prevent leakage into the peritoneal cavity, it should be the surgeon's aim, I think, to secure adhesive inflammation by cauterization of the preliminary incision first, and to open the abscess cavity only when a protective wall of lymph has been thrown out.

But this may involve a delay of several days, and if marked symptoms of septic absorption supervene before the adhesions are formed, then, as a temporizing measure, aspiration with a capillary trocar may be resorted to.

919 WALNUT STREET, Dec. 20, 1888.

NOTE ON THE TREATMENT OF TONSILLITIS BY SALICYLATE OF SODA.

BY W. A. DEWOLF SMITH, M.D., L.C.P.&S. QUE.,
OF NEW WESTMINSTER, B. C.

ABOUT the 15th of September last, I was consulted by Mr. W. H. F. about his throat. He had been a sufferer from repeated attacks of tonsillitis, and on this occasion his throat presented the usual symptoms of that disease.

As on former occasions, various remedies, such as guaiacum, had been tried without any beneficial results, the patient was anxious to get the thing over with as soon as possible. He was accordingly made to steam the throat frequently, and had continued this for three or four days without any advantage, when my attention was directed to a note in THE MEDICAL NEWS of June 2, 1888, on the treatment of tonsillitis by salicylate of soda. I accordingly put the patient on a mixture containing salicylate of soda, with the gratifying result of finding in a day or two the soreness and swelling disappear from Mr. F.'s throat.

After a few days one of his tonsils again enlarged, although there was no pain, and I feared even then that an abscess would form as usual, but perseverance in the use of the salicylate met with its reward. The swelling disappeared in a couple of days and has not troubled him since.

The drug was given in the same dose and manner as recommended in the note referred to above.

MEDICAL PROGRESS.

A Case of Sulfonal Poisoning.—DR. BORNEMANN records in the *Deutsche med. Zeitung*, No. 95, the following case of sulfonal poisoning: A physician, addicted to the morphine habit, which he had acquired in trying to overcome headache during the past twenty-eight years, and who had visited ten "cure-institutions," came at last into the institution of Dr. Bornemann. On the evening of the 10th of May, the patient took for the first time thirty grains of sulfonal, without effect, and it was only after a second dose of fifteen grains, and one-third of a grain of morphia subcutaneously, that he fell into a sound sleep of eight hours duration. May 11th, forty-five grains of sulfonal were given at bedtime, without morphia; he slept till morning. May 12th, one-third of a grain of morphia, at bedtime sixty grains of sulfonal; no sleep. During the same night (1 A.M.), thirty grains of sulfonal; no sleep. Patient left his bed, acted like a drunken man, and fell several times; and when attempting to take hold of an object, he would miss it. Pupils contracted. On the morning of May 11th, patient slept four hours. Even while in bed, he believed himself drunk. On the same evening, he complained of the sensation of having two heads, two pairs of arms, and double vision. From that time on, the administration of sulfonal was discontinued, although patient kept constantly asking for it. It was not until May 18th that all apparent symptoms of poisoning disappeared.—*Wiener med. Presse*, No. 50.

Treatment of Ophthalmia in the Newborn.—At a recent meeting of the Society of Medical Science, of Lyons, this subject being under discussion, DR. GRANDCLÉMENT spoke very highly of nitrate of silver and sublimate, which he stated are the most powerful antagonizers of the gonococcus of Neisser. In support of this statement, he called attention to the experiments of Dr. Kreiss, of Vienna, who had arrived at the same conclusions.

Hence, the treatment of ophthalmia of the newborn should consist in cauterizing every twelve hours the palpebral conjunctiva and the conjunctival cul-de-sac with the following solution:

℞.—Nitrate of silver . . . 3 grains.
Distilled water . . . 1 drachm.—M.

Between the intervals of cauterization, the eyes are to be washed with a strong solution of sublimate, or with

lukewarm water, or with a ten per cent. solution of bicarbonate of soda, as practised by Dr. Castellan.—*Revue de Thérapeutique*, Dec. 6, 1888.

Urinology of Neurasthenia.—DR. DANA, from a study of the urinology of neurasthenia, deduces the following conclusions:

1st. The importance of classifying neurasthenic types.

2d. The existence of different conditions of the urine, corresponding to different forms of neurasthenia.

3d. The existence of a functional inadequacy of the kidney in certain types of neurasthenia.

4th. The greater frequency of heavy urines in irritative and diathetic forms of neurasthenia.

5th. The existence of a polyuria in certain forms of neurasthenia.

6th. The importance of recognizing these conditions by measuring and testing daily amounts.—*Cincinnati Lancet-Clinic*, Dec. 22, 1888.

Action of Phenacetin.—At a recent meeting of the Royal Academy of Turin, DR. PESCE reported the following results which he has obtained with phenacetin:

Phenacetin produces a marked and prolonged diminution of the temperature, leaving the patient, at the same time, in a stimulated condition. The fall and, later on, rise in temperature, is a slow and gradual one. With three-fourths of a grain at one dose, the temperature is generally reduced from 3½° to 5½° F. This fall does not, as a rule, produce any annoying or dangerous symptoms, save a general sweating. Phenacetin can be classified amongst the anti-rheumatics, in which disease it lowers the fever, removes the pain of the joints, and thus allows of freer motion. It will also be found of use in neuralgia, cephalalgia, migraine, and other irritating conditions of the nervous system.

As a rule, three-fourths of a grain doses will be found sufficient; if necessary, they may be repeated every two or three hours.—*Deutsche med. Wochenschrift*, Dec. 6, 1888.

The Diagnostic Value of the Tolerance of the Iodides in Syphilis.—DR. J. WILLIAM WHITE, in an article upon this subject, closes with the following conclusions:

1. Personal idiosyncrasy is so strong a factor in relation to the toxic symptoms produced by the iodides, that it quite overshadows any possible influence due to the existence of syphilis.

2. There are no satisfactory theoretical grounds for believing that syphilis in any stage prevents the production of iodism by a process of neutralization, and this is particularly unlikely to be true as regards the latter stages.

3. It is therefore most unsafe to base any diagnostic conclusion upon the presence or absence of toxic symptoms (iodism) after the administration of full doses of the iodides.—*Therapeutic Gazette*, December, 1888.

Painless Extraction of Teeth.—DRS. HÉNOGUE and FRIDEU, of Paris, state that the extraction of a tooth may be rendered painless by spraying the neighborhood of the external ear with ether.

The anæsthesia of the trigeminus so produced extends to the dental nerve, and thus renders the production of general anæsthesia needless.—*Popular Science News.*

For Sweating of the Feet.—

℞.—Salicylic acid . . . . . 3 parts.
Starch . . . . . 10 "
Talc. . . . . 87 " —M.

Or,

℞.—Salicylic acid . . . . . 2 parts.
Mutton tallow . . . . . 100 " —M.

Apply to feet.

(The last formula is used in the Prussian army.)—*Les Nouveaux Remèdes*, Dec. 8, 1888.

How to Accelerate the Growth of Bones in Man.—A novel suggestion is made by Dr. Schneller, of Berlin, for the purpose of accelerating the growth of the long bones, with a view to the prevention or rectification of deformities arising from the unequal length. It is well known that irritation of the diaphyses of long bones brings about an increased blood supply, which, by increasing nutrition, stimulates bone formation, while lesions of the epiphyses produce an arrest of development, at any rate for the time being. Ollier is reported to have remedied the deformity resulting from a short radius by destroying the intermediary cartilage of the ulna, and putting a stop to further growth. Dr. Schneller has improved on this rather risky procedure. He inserts a nickel iron spike into the diaphysis of the short bone, allowing it to remain *in situ* for nine days, when he withdraws it and allows the wound to heal. When cicatrization has taken place he applies an elastic band moderately tightened, higher up the limb, so as to increase, by stasis, the quantity of blood in the limb. In all the cases treated by this method, the difference in length of the bones rapidly decreased, and atrophied muscles acquired fresh functional activity and became larger. He mentions a case of genu valgum in which he succeeded in restoring symmetry and remedying the preëxisting laxity of the ligaments. —*Medical Press*, December 12, 1888.

Treatment of Eczema.—The treatment, which consists in the isolation of each pustule, is proceeded with as follows:

1st. *External medication.* Continue the application of soft poultices until the crusts covering the pustules have become detached; then cover each of the ulcers with Vigo's plaster, which is to be left on for three days, unless previously detached through the process of suppuration. Under this covering, budding and cicatrization will take place rapidly.

2d. *Internal medication.* The diet to consist of rare meats, fresh vegetables, and plenty of wine. In most cases, the addition of iron and quinine will be beneficial. —*Revue Gén. de Clin. et de Thérap.*, October 25, 1888.

Buckthorn for Toothache.—The peasants of the southern part of Russia have the habit of overcoming an attack of toothache by gargling with a decoction of buckthorn (Rhamnus catharticus). DR. GRETCHINSKY, having prescribed gargles of this decoction, to be repeated every five minutes, observed that the toothache was dispersed within thirty minutes, but in its stead was left a sensation of itching and a dull pain. To overcome this phenomenon entirely, the author ordered the insertion of small cotton pledgets saturated with this preparation. The result was excellent. To prepare this decoction, put one

hundred parts of the bark into so much boiling water that, after filtering, two hundred parts of the water remain, to which add ten parts of alcohol.—*Druggisten Ztg.*, No. 44, 1888. *Les Nouveaux Remèdes*, Dec. 8, 1888.

Diuretic Action of Mercurial Preparations.—DR. WLADYSLAW BIEGANSKI, in a thesis upon this subject, concludes with the following *résumé:*

1. The action of calomel and other mercurial preparations is a diuretic one; under its influence the secretion of urine is augmented.

2. This action is observed to the greatest advantage in the œdema of cardiac origin.

3. The diuretic action is observed, no matter what preparation or method of administration is used; the most marked action, however, is noticed after subcutaneous injections, less so when given by mouth, and the least marked when used in the form of inunctions.

4. Small doses of mercury do not produce diuresis, only large doses.

5. The diuretic action of mercury is probably due to its irritant action upon the kidneys.—*Archiv f. klin. Med.*, Bd. 42. *Centralbl. f. d. ges. Therapie*, December, 1888.

An Ointment for Ciliary Blepharitis.—

℞.—Ointment of zinc, White precipitate . . āā 7½ grs.
Vaseline . . . . . ʒiij.

Or

℞.—Oil of birch, Oil of eucalyptus . . āā 7½ grs.
Vaseline . . . . . ʒiij.—M.

Rub some into the borders of the eyelids three times daily.—*L'Union Médicale*, December 8, 1888.

Treatment of Syphilis with Hypodermatic Injections of Sublimate in Olive Oil.—Of late, many authors have written about the subject of hypodermatic injections of mercury in the treatment of syphilis. DR. CRUYL has tried the method in numerous cases, and adds his experience to the unsatisfactory results of Scarenzio, Balzer, and Neisser, which are that injections thus made cause irritations, indurations, and abscesses. It was to avoid the latter that the author tried the injections of the metal with olive oil as a medium, with the results, that out of two hundred injections thus made, not one was followed by induration or pain.

The mode of procedure is as follows: The needle of the syringe having been rendered thoroughly antiseptic, is filled with the injecting fluid, and forced deep into the subcutaneous tissue in the dorso-lumbar region.—*Revue Gén. de Clinique et de Thérapeutique*, December 6, 1888.

On the Hypodermatic Use of Morphia.—DR. EDWARD O. DAILY, M.A., M.R.C.P., in a thesis upon this subject, concludes with the following well-founded remarks:

1st. Never inject a larger quantity than one-sixth of a grain in a person unaccustomed to morphia.

2d. Never give an injection of morphia to a person suffering from hysteria.

3d. Never give an injection to a person cured of the morphia craving.

4th. Never hand over the syringe to the patient himself.—*Medical Chronicle*, December, 1888.

Faradic Electricity in Hysteria and Epilepsy.—DR. DIDIER, in a paper upon this subject read before the National Society of Medicine of Lyons, presented the following conclusions:

1st. Of all the means employed heretofore to arrest and possibly to abort an attack of hysteria, faradic electricity is without doubt the best. It has arrested attacks of convulsive hysteria in all the cases in which it has been tried, and in two cases of hysterical epilepsy. Further, this method possesses great advantages over compression of the ovaries, which, if too often repeated, may be followed by grave results.

2d. Faradization permits, in difficult cases, of a diagnosis being made between epileptic and hysterical attacks, as in the former the attack is not modified, while in the latter it is arrested.

3d. By means of faradic electricity, one can distinguish in a patient suffering from two neuroses, at one time, the symptoms which belong to hysteria since they are arrested in their course, and epileptiform manifestations which run their complete course, notwithstanding the efforts to arrest them.

4th. The mode of operation consists in applying the electrodes of a faradic current of moderate intensity along the course of the aura—that is, along the epigastric region and to the anterior portion of the neck. Application is then to be renewed only during the tonic or clonic period; one electrode is then placed to the neck and the other is taken in one hand, or else both electrodes are taken in both hands.

5th. Besides possessing an abortive power over the hysterical crisis, faradization has at the time other curative effects, which are too well known to need mentioning here.—*Lyon Médical*, December, 1888.

New Operation in Empyema.—DR. M. S. SUBBOTIN, of Kharkoff, describes, in the *Vrach* (No. 45), a new operation he has devised for opening the thoracic cavity in empyema, with the view of obviating the danger arising in Estlander's operation, and in the modifications of it practised by Schede and Sprengel from the extensive raw surface which is necessarily allowed to remain in contact with the purulent discharge. Prof. Subbotin suggests that in cases in which the lung itself is free from disease, the unyielding nature of the thoracic wall may be overcome without the removal of ribs by simply cutting them through; also, that if a rib is divided in two places, and the intermediate portion removed, the chest-wall will become flexible, and may be pressed inward, so as to lessen the cavity of the empyema, and in this way assist to put an end to the suppuration. After thinking out a plan based on the above considerations, he determined to apply it in operating on a case under his care in the Kharkoff clinical wards last June. The patient having been chloroformed, an incision was made along the seventh rib, which was then stripped of its periosteum, and excised to the extent of seven or eight centimetres. An extensive opening was here made into the pleural cavity. After the pus had been evacuated, the cavity was carefully cleansed, and the opening well covered with gauze, and a gauze compress applied. An incision was then made along the border of the pectoralis major, about five centimetres in length, exposing the sixth, fifth, and fourth ribs, and these were cut away (the periosteum not being left) with forceps until the rib became movable.

Another incision was then made in the line of the posterior fold of the axilla, exposing the same ribs, which were again divided as before; the wounds were then sutured and dressed with gauze, a large, thick pad of the same substance being applied outside, with a good compress bandage round the thorax. The upper wounds were kept from communication with the empyema. When, after a few days, the intra-thoracic wound was dressed, a drainage tube was put in. The case recovered, but three months after the operation there was still a small sinus which continued to discharge.

The advantages claimed by Prof. Subbotin for his operation are: the small raw surface which is left in contact with the purulent matter; and the firm but movable portion of the thoracic wall which can be pressed inward by bandaging, so as to diminish to a considerable extent the size of the cavity.—*Lancet*, December 15, 1888.

Iodol as an Internal Remedy.—DR. DAUTE CERVESATO, of Padua, gives in the September number of *Lo Sperimentale*, an account of his observations on the internal administration of iodol, the first of which were made upon scrofulous patients, in whom the remedy acted very favorably in whatever form it was given. It acted best when the lymphatics had not as yet undergone purulent infiltration. In scrofulous affections of the mucous membranes, such as scrofulosis of the nose, or scrofulous otitis, the beneficial action was but limited, and still more limited in scrofulous affections of the skin. The author administered the iodol to children in daily doses of 8–15–23 grs., continued from two to three months, with good results. The internal administration was supplemented by external inunction of an iodol salve (1 part to 15 of vaseline), or by iodol insufflations. The remedy was well borne; the appetite and digestion generally improving.

In diseases of the respiratory organs, the drug was given in from 15 to 45 gr. doses, in conjunction with the inhalation of the following solution:

Iodol, 1 part dissolved in 5 parts of heated alcohol, filtered; 10 parts of glycerine, heated to 60° or 70° F., were then added, and before the solution cooled, 10 parts of water were also added. For each inhalation, of which two or three were taken daily, 4 drachms of this solution suffice.

In the first stages of laryngeal tuberculosis, great improvement was observed, but still greater beneficial results were obtained in acute and chronic laryngitis. In tertiary syphilis, the specific action of this drug was well marked. Two cases of syphilitic suppuration of the roof of the mouth and syphilitic ulcers of the pharynx, healed under the internal administration and external applications of iodol, continued for two months. Internally the iodol was administered in from 15 to 45 gr. doses, while locally the following was applied:

℞—Iodol	15 grs.
Alcohol	ʒjv.
Glycerine	℥j.

In none of the cases treated were any symptoms of iodism observed.—*Wiener med. Presse*, No. 49, 1888.

Therapeutic Action of Hyoscin.—DR. KNY, of Strassbourg, has tried the muriate of hyoscin (Merck) in a number of cases. The subcutaneous administration was soon discontinued. Taken by the mouth the results obtained were more satisfactory. Eighty-eight patients of the Strassbourg Insane Asylum were given 3000 single doses; after the lapse of one to two hours, a six to eight hours sleep was obtained in 82.2 per cent. of the cases. Most failures were observed in cases of insomnia without motor excitement, while the best results were obtained in insomnia accompanied with marked motor phenomena, as, for example, in mania and paralysis. The dose was from $\frac{1}{120}$ to $\frac{1}{84}$ gr. As a rule, patients soon became accustomed to this amount, necessitating an increase in the quantity administered, which was gradually increased to $\frac{1}{72}$ gr. the maximum dose. In only one case did the remedy prove to be inactive.

The disagreeable symptoms produced by hyoscin are dryness of the throat and great thirst, while its advantages are absolute tastelessness and great solvency and cheapness.

Attacks of recent mania were cut short by this remedy. In paralysis agitans and multiple sclerosis, it proved to be a palliative remedy. Digestive disturbances, of short duration only, were noticed in some cases.—*Deutsche med. Wochenschrift*, December 6, 1888.

Ocular Antisepsis.—*Oxycyanide of mercury* is a very stable salt, very soluble, a non-acid, does not precipitate albumin, and attacks metals but slightly. Patients bear it better than the bichloride, and it acts better upon the *micrococcus aureus* than the latter. DR. CHIBRET employs this salt in solutions of 1 to 1500, which he prescribes under the form of eye-baths, because the effect is more powerful when its direct contact with the mucous membrane is prolonged. After operations for cataract he also employs it for irrigating the anterior chamber, having previous to the operation allowed his instruments to rematn in the solution for several hours.

Hirschberg, of Berlin, employs a sublimate solution of 1 to 5000 as the excipient of his collyria for a cataract case and Mayen uses a solution of 1 : 2500 for a wash in the same operation.—*Bulletin gén. de Thérapeutique*, November 20, 1888.

Creasote in Chronic Lung Affections.—DR. SOLTMANN reports having administered creasote in eight phthisical cases with satisfactory results. He prescribes:

℞.—Creasote	gtt. 4–14.
Spirits of ether	gtt. 6–12.
Water.	℥1½.
White sugar	℥2½.

One teaspoonful every two hours, the entire quantity to be taken in two days.

Increase of appetite and body-weight and a disappearance of the lung symptoms were noticed in most of his cases.

Parenchymatous creasote injections in phthisis pulmonalis (a 3 per cent. oil solution) were tried by DR. ROSENBUSCH with good results. The injections were made in the two intercostal spaces or in the supra-spinata fossa.—*Deutsche med. Wochenschrift*, December 6, 1888.

Operation for Excision of Eyeball.—DR. COPPEZ, of St. John's Hospital, Brussels, publishes, in the current number of *La Clinique*, the details of a method of enucleation which he considers to be easier and simpler than the methods of Bonnet and of Tillaux now in use. The

patient having been anæsthetized, and the eyelids separated by a speculum, a thread is passed transversely through the cornea by means of a curved needle; the ends of the thread are knotted, and the loop held in the left hand. By traction on this loop the eye is drawn slightly forward, and with a curved scissors the conjunctiva is divided close to the corneal edge. The subconjunctival tissue is then torn through, and the tendons of the recti muscles come into view and are divided; next, the tendons of the oblique muscles, and, finally, the optic nerve. Dr. Coppez claims for his operation that it may be practised with fewer instruments—a curved needle, scissors, and a speculum; that the optic nerve may be divided more directly and at a greater depth in the orbit, which, in the case of malignant tumors, is of great importance; and that the consequent hemorrhage is less considerable than in the ordinary operations. The only objection to it, he thinks, is that the globe might be rendered flaccid by the escape of the aqueous humor through the needle-holes, but that is of little importance.—*Lancet*, December 15, 1888.

Salol in Skin Affections.—DR. EDMUND SAALFELD, of Berlin, reports successful results obtained with salol in the treatment of various skin affections. According to his experience, a 5 to 8 per cent. ointment of salol with vaseline or with balsam of Peru and cold-cream, acts better than the ordinary ceratum plumbi subacetat., or the ointment of salicylate of soda.

Remarkably prompt results were obtained in some cases of impetigo contagiosa. One patient suffering from sycosis simplex, which had spread over the entire face and neck, obtained marked relief from salol ointment, to which Dr. Saalfeld subsequently added sulphur and carbonate of potash, with the satisfaction of seeing the disease entirely disappear.—*Deutsche med. Wochenschrift*, November 22, 1888.

Pastes in Dermatology.— Since Lassar introduced into dermatological practice the use of salicylic paste, the utility of pastes in irritable conditions of the skin has been abundantly proved. DR. GRUENDLER, of Hamburg, has recently (*Monatsh. f. Prakt. Derm.*, No. 20) made some interesting experiments in Dr. Unna's laboratory on the relative capacity for the absorption of water inherent in various powders, which might be used in the preparation of these pastes. He found that carbonate of magnesia had remarkable qualities in absorbing water, and therefore ought to be an excellent ingredient for the formation of a paste. Unfortunately, however, pastes made of a mixture of fat and carbonate of magnesia do not possess the proper consistence. When, therefore, this highly absorbent quality of carbonate of magnesia is desired, it is advisable to combine it with the other powders commonly used. For example, fifty parts of oxide of zinc or starch may be mixed with ten parts of carbonate of magnesia, and the whole rubbed up with fifty parts of fat to form a paste, or as a simple absorbent powder it may be very conveniently used mixed with oxide of zinc.—*British Medical Journal*, Dec. 15, 1888.

Paralysis after Pneumonia.—DR. B. H. STEPHAN mentions in the *Weekblad* twenty-five cases of pneumonia which came under his observation, in which he thinks two points are of special importance. The first is the high death-rate, nine out of twenty-five patients, or thirty-six per cent., dying; the second point is the adynamic or asthenic character of the pneumonia, in which the brain symptoms predominated and the pulmonary affections were secondary. Dr. Stephan thinks that these considerations, and the complications of a typhoid or bilious nature which may arise, point to the conclusion that pneumonia, under certain aspects, must be regarded as "specific fever." He believes that adynamic pneumonia is more frequent now than formerly, which leads him to the conclusion either that the constitution of individuals predisposed to pneumonia must have altered, or that the causes of pneumonia itself are changed. Dr. Stephan considers it not improbable that the first hypothesis may be correct—namely, that the frequency of neurasthenia in the present day shows the weakening of the cerebro-spinal system. A surgeon told Dr. Stephan he had practised bloodletting with the most successful results for thirty years at Drente, but that of late, in Holland, he had become very shy of doing so in inflammatory affections of the chest. The question suggests itself whether former practitioners acted wrongly in their treatment of pneumonia, or whether the physical condition of patients is now altered.

Out of the twenty-two adult patients treated by Dr. Stephan, twenty were men exposed to very decided changes of temperature. The fact is undoubted that more men than women are attacked, and Dr. Stephan considers it very probable that chills and infection are directly connected. The theory that bacteria are a cause of pneumonia appeared to him a plausible explanation. If the pneumococci are only waiting an opportunity to attack us, then the hypothesis that a lesion in the lung is favorable to their development is intelligible. What may happen in the case of traumatism may happen in the case of a chill. In a healthy condition the body is entered by countless bacteria, which are kept in check by the normal resisting power of the healthy tissues, but as soon as the normal equilibrium is upset, one or other of the organs is attacked and becomes the sport of these bacteria.

Dr. Stephan mentions two cases of paralysis ushering in pneumonia; the first was a man, who was suddenly attacked with apoplectic symptoms. In two days the whole of the right lung was solid with pneumonia; the pneumonia ran a regular course, but the paralysis of the arm, leg, and facial muscles did not disappear completely for three months. In the other case, a child of two years, the pneumonia was preceded a few hours by strong convulsions, after which symptoms of meningitis became well marked; the lung disease followed, and the child died on the eleventh day. In conclusion, Dr. Stephan remarks that paralysis has sometimes occurred at the commencement, during the course, or at the end of an attack of pneumonia; and where there has been a necropsy, either meningeal symptoms have been found or else there were no macroscopic or microscopic lesions. The most probable explanation of the first category is that the pathological anatomical lesions rest on the extra-pulmonary localization of the pneumonia poison. In the second, the explanation probably is that the pneumonia poison, either directly or through the medium of the bloodvessels, occasions dynamic disturbances in the nerve-centres or nerve-trunks.—*British Medical Journal*, December 15, 1888.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JANUARY 5, 1889.

EYE SYMPTOMS AND CEREBRAL LOCALIZATION.

THE fact that, of the twelve pairs of cranial nerves, six pairs are concerned in supplying the eye and its immediate accessories, suggests, but inadequately, the importance of what are known as eye-symptoms in the diagnosis of cerebral disease. The minute differentiation and definite association of function here exhibited, as in convergence and conjugate deviation, in binocular vision, and the connection of certain particular portions of the retina with certain portions of the cerebral cortex, open great possibilities of accuracy and refinement in cerebral localization.

The fact that several of the nerve trunks in question run comparatively long distances within the cranium, after emerging as trunks from the brain mass, makes it almost certain that one or more of them will be involved in any considerable disease of the base of the brain, or its membranes. The palsies resulting from such involvement are very fairly understood, and by their grouping or association are very important in localizing the lesions causing them. Many well-reported cases of such palsies are on record, and available for present or future study; and as the anatomical basis of connection is obvious and generally understood, this kind of localization is well advanced. But when we come to the localization of lesions involving the cortex, the commissural fibres, or even the ganglia at the base of the brain, we find that the intelligent study of the subject is just beginning.

The really important literature of the subject consists of reports of only a few isolated cases that have been well studied, and a considerable accumulation of results obtained by physiological experiment, the value of much of which is yet to be determined. The important practical deductions to be based often on a single well-studied case are full of encouragement to the observer. It may well happen in the present state of our knowledge, that a single well-conducted autopsy, added to a careful observation of symptoms, will be enough to save one life, or even many lives. But a case to be of much value must be thoroughly studied, and by the aid of all the light obtainable from the records of predecessors in this direction. Because of its omissions all the older literature of brain diseases is worthless. And in this connection it should be mentioned that negative results of carefully applied tests may give just as much light as to the connection of lesion and symptoms as any positive results can give.

Attention to this subject has heretofore been too much confined to a few specialists, and the group of operators who will soon be spoken of as "cerebral surgeons." Mr. Henry R. Swanzy, of Dublin, in the "Bowman Lecture" for 1888, before the Ophthalmological Society of the United Kingdom, which is published in the London weeklies, places a good *résumé* of our present knowledge of the subject before the ophthalmic surgeons, who must frequently have opportunities of studying the eye-symptoms of brain disease, at times when their diagnostic significance is most certain. For it is usually the permanent symptoms to which most importance is to be attached for purposes of diagnosis; it is the palsy that remains long after an otherwise complete recovery from apoplexy, or the spasm that appears before the case is suspected to be one of cerebral degenerative change, that best localizes the mischief. These are commonly manifestations of the loss or impairment of function in the part directly affected, and hence are called the "direct" symptoms. When the morbid process is at its height, the part in which it is located is liable, by its reaction on other parts with which it is intimately connected, to pervert or hold in abeyance their function also; although the parts thus secondarily affected may, themselves, be perfectly healthy. In this way arise the symptoms which have been called "indirect," and which may greatly increase the difficulty of localizing the lesion. Swanzy proposes to call these latter "distant symptoms," rather than "indirect," which, he

agrees with Dr. Gowers in thinking, conveys a false conception of their nature.

The most common symptom of focal disease, derivable from the motor apparatus of the eye is conjugate deviation of the visual axes; which are turned toward the side of the lesion in paralysis, and from it in spasm. That a cortical centre governing this movement exists, cannot be doubted, but its location is not yet certainly ascertained. The difficulty in fixing it arises from the same condition as that which causes the frequency of interference with its function, and which robs its occurrence of any special significance; that is, from its wide connections and consequent liability to "distant" or "indirect" involvement. From our common and instinctive acts we would expect the centre for turning the eyes to one side would be connected more or less intimately with the centre for hearing, and all centres for touch, and even for motion for that side. The symptom may, however, be of importance in indicating the side of the lesion, when, as in coma, other symptoms cannot be elicited. The existence of other cortical centres, which we are as yet unable to localize, is indicated by a condition, in a sense, the opposite of conjugate deviation, in which one eye is turned downward and outward and its fellow upward and inward; or by paralysis of upward and downward movement alone, or by ptosis without other oculo-motor paralysis. Nystagmus, too, is of little value for localization.

As, however, we leave the cortex, and come to consider focal lesions of the basal ganglia and tracts, the localizing value of the symptoms increases. Thus, ptosis or other third nerve paralysis, partial or complete, with simultaneous hemiplegia affecting the opposite side, indicates disease of the crus cerebri; while paralysis of the sixth nerve, with simultaneous crossed hemiplegia, indicates a focal lesion of the pons. Isolated and complete paralysis of the third, fourth, or sixth nerves is almost always basal—that is, trunkal. In paralysis of the fifth nerve, the occurrence of neuro-paralytic ophthalmia points to disease involving the nerve trunks; its absence pointing rather toward the nucleus or the commissural fibres in the pons as the seat of the lesion. The state of the pupil has always attracted attention in cerebral disease, yet so imperfectly have the mass of cases been observed and recorded that we know scarcely as much of the significance of mydriasis and myosis as of other third nerve symptoms. Loss of the light-reflex has much the same significance in blindness that neuro-paralytic ophthalmia has in fifth nerve palsy, pointing to a trunkal and not a central lesion.

In hemianopsia we have a symptom which rivals in importance those affections of the motor centres for speech, and the various movements of the face and upper extremity, that have played such an important part in the history of cerebral localization. There is no centre in one-half of the brain for the opposite eye; indeed, it is at least uncertain if such a condition as a crossed amblyopia occurs, although good observers have described it. But the right half of the brain is concerned with the perception of objects to the left, and, therefore, is in connection with the right half of both retinas, and *vice versa*. Loss of function of one cortical centre or of the tracts connected with it, leads to inability to see anything situated to the other side of the visual axis, or homonymous hemianopsia, the only kind of half-blindness that is of frequent occurrence, or very general interest. In connection with it, the presence or absence of the light-reflex of the pupil when light is thrown on the blind half of the retina, tells whether the lesion is central or situated in the so-called optic tract. There can now be no doubt that the visual centre is situated in the occipital lobe; included mainly in the cortex of the cuneus and superior occipital convolution. At least, that this is the centre for form-vision. A few well-recorded cases indicate that the centre for color-vision is so entirely distinct that it can be functionally destroyed, causing, when the lesion is limited to one hemisphere, hemiachromatopsia, without serious impairment of form-vision. This centre for color-vision seems to be located rather in the posterior part of the superior and inferior occipito-temporal convolutions. Again, it is not impossible that there is a centre for the so-called light-sense, distinct from those for form and color. More than this, cases of incomplete hemianopsia would seem to show that even smaller subdivisions of the retina are represented each by its particular subdivision of the cortex.

The localization of lesions causing "mind-blindness," "word-blindness" or alexia, and "dyslexia" or inability to read more than a few words consecutively, because of a sense of dislike or disgust engendered by the effort, is as yet not sufficiently certain to make them of much practical importance; but the little we do know in this direction opens up a most inviting field for further

study. In the study of focal disease of the brain it is of great importance, as Swanzy points out, that not only shall symptoms be studied and recorded with the skill and accuracy of the specialist; but that the necropsy should be conducted with the greatest precision, and the examination of the brain, in all cases, entrusted to skilled pathologists and microscopists.

IN New York City, the Presbyterian Hospital has opened a large "annex," as it is called, to be used as an out-patient department. The Montefiore Home for men having chronic or incurable disease is completed. Both of the above are non-sectarian institutions.

At Bellevue Hospital the new training-school for male nurses is in operation, a class of twelve young men being the first to avail themselves of this newly established drill. At the Cancer Hospital, which has been hitherto wholly devoted to the treatment of females, it is proposed to complement its charitable work by an additional pavilion for males; this will be built and endowed by Mr. John Jacob Astor.

A large brewing interest, on Staten Island, proposes to construct a free Infirmary for its employés, among whom the sickness-rate is high, accidents are frequent, and the people, as a rule, improvident and inclined to fall back on their employers in times of disability. At Brooklyn, a North-German or Platt-deutsche hospital is under consideration, a considerable sum of money having been acquired for the purpose.

At Elmira a handsome little hospital has been given to the public by members of the Ogden and Arnot families.

From this it will be seen that, in New York State at least, the poor are not likely to suffer in the near future for the want of gratuitous medical service.

OUR excellent contemporary, *The Canadian Practitioner*, will be issued hereafter as a semi-monthly, under the same editorial management that has won for it a leading place in Canadian medical journalism.

THE case of sextuple birth reported to have occurred in Navarro County, Texas, which has been going the rounds of the papers, both lay and medical, and to which reference was made in our issue of December 15th, upon investigation, we learn, "originated in the fertile imagination of an ingenious reporter, and is fiction without the least foundation of fact." We are also further informed by a prominent physician in that locality, that no such incident has occurred there and no family of the name given in the newspaper report resides there.

DR. CHARLES V. CHAPIN, who has been Superintendent of Health of the city of Providence, R. I., since 1884, has now been elected to the additional office of City Registrar, to succeed Dr. E. M. Snow, deceased, who had held the position continuously since 1855.

THE following committee has been authorized to receive subscriptions in America for the "Langenbeckhaus," which is to be erected in Berlin as a memorial to the late distinguished surgeon whose name it will bear: Dr. von Herff, of San Antonio, Texas, chairman; Dr. Baumgarten, of St. Louis; Dr. Ferrer, of San Francisco; Dr. Emil Fischer, of Philadelphia; Dr. A. Jacobi, of New York; Dr. Löber, of New Orleans; Dr. Mendel, of Milwaukee; Dr. Salzer, of Baltimore; and Dr. Lange, of New York, secretary.

FROM a London letter to the *Medical Press* of Buffalo, we quote a curious illustration of the extent to which specialism has become popularized abroad:

"Shortly after coming to London I was invited, through the courtesy of one of England's most noted surgeons, to be present at one of his operations. During the operation a telegram was handed to him which he read and handed over to me. It ran thus: 'Can you recommend us a good surgeon for the elbow-joint?' The joke about the matter was that at the same time he was treating the ankle-joint of another member of the same family, a sister of the patient for whom the inquiry was made and living in the same house. Other and equally absurd examples often come up from time to time, and make one wonder where the matter will end."

The correspondent argues that this incident shows that the hold of specialism is far stronger over the English public than it is in this country.

THE American Association for the Study of Inebriety offers a prize of one hundred dollars for an essay on the lesions of chronic alcoholism capable of microscopic demonstration. Each essay must be accompanied by microscopic slides which will sustain the arguments or positions of the writer. The competition ends October 1, 1890, by which date all essays should be in the possession of Dr. W. H. Bates, 175 Remsen Street, Brooklyn, N. Y.

SOCIETY PROCEEDINGS.

THE PHILADELPHIA NEUROLOGICAL SOCIETY.

Stated Meeting, November 26, 1888.

THE VICE-PRESIDENT, CHARLES K. MILLS, M.D., IN THE CHAIR.

DR. MILLS made some remarks on the classification of

DYSTROPHIES,

arranging them into cases of muscular, neural, spinal, and cortico-spinal origin. He referred to the classifications of Erb, Gray, and Sachs. Speaking of dystrophies as complicating or added affection, he said that, in a considerable list of cases, a dystrophic condition is a marked, but not the only feature, of certain well-known nervous diseases, as, for example, glosso-labio-laryngeal or bulbar paralysis, ophthalmoplegia externa or progressive paralysis of the external ocular muscles, and true poliomyelitis in its various types—acute, subacute, and chronic.

Atrophy of the tongue is occasionally seen as an isolated affection, but more commonly in association with other diseases, such as ophthalmoplegia externa, glosso-labio-laryngeal paralysis, or regular or irregular forms of sclerosis. Whether an isolated affection or simply an incident of another disease, it may be unilateral or bilateral. Raymond and Artaud have recorded a case of unilateral degeneration of the hypo-glossal nucleus in tabes, and other cases with acute apoplectic onset have been reported. Westphal demonstrated a similar interesting specimen from a patient who had ophthalmoplegia externa and complete paralysis of both eyeballs, and atrophy of the antero-lateral portion of the left side of the tongue.

With almost every form of sclerosis described as a separate disease, a dystrophy may, at times, be associated, as his own experience had shown. In posterior spinal, lateral, amyotrophic lateral, or disseminated sclerosis, early or late may develop progressive muscular atrophy of one or more extremities; or a bulbar paralysis of either the glosso-labio laryngeal, or of the external ocular type. Such cases are included in the list to be presented at the present meeting. It might be worth while to discuss the question of the identity or not of progressive muscular atrophy and amyotrophic lateral sclerosis, some authorities denying the justice of any distinction. Charcot regarded the degeneration of the pyramidal tracts as primary, and the affection of the horns as secondary, and hence the name given by him.

Besides the joint affections which occur in the course of posterior sclerosis and other spinal diseases, cases are sometimes seen in which widespread disease of the joints is associated with equally widespread atrophy, giving a form of arthritic muscular atrophy to which Gowers devotes a few pages, and which has been discussed by Duchenne, Vulpian, Paget, and others. The atrophy which commonly attends inflammation of the joints is not to be altogether explained by disuse. The joint disease may be the cause of the atrophy, or the two may be associated and due to a common cause. Paget speaks of these cases as reflex atrophies due to disturbance of some nutritive nervous centre, irritated by the painful state of some of the sensitive nerve fibres. In some of the cases of widespread arthritic atrophy the joints are extremely painful, and in some not.

Dr. Mills presented notes, and exhibited patients, illustrating some unusual forms of dystrophies.

CASE I. *Progressive muscular atrophy of traumatic origin.*—J. G., aged forty-four years, white, born in Germany, laborer, was admitted to the Philadelphia Hospital March 1884. In June, 1876, he fell from a scaffold and sustained severe injuries in the cervical region, for which he was treated at the Pennsylvania Hospital for two years, when he was discharged, able to do light work. In December he resumed work as a stonecutter, and considered himself well up to February, 1884, when he fell from a scaffold, and again hurt his spine, this time in the dorsal and lumbar region. During five weeks after the accident he lost all control of the bladder. On several occasions after his admission he passed blood with his urine. Four weeks after the accident he felt two constricting bands, one at the level of the nipple, and the other just below the umbilicus. The upper band tightened at the least movement of the arms, almost preventing respiration, and on attempting to rise, the lower band tightened. He complained also of a burning sensation in the soles of his feet.

In 1884 it was noted that he was able to walk; but had marked atrophy of the muscles of the shoulder and arm. The thumb was strongly flexed, and the fingers were contractured. He also had some atrophy of the muscles of the lower extremities. Recent examination shows extreme wasting of the muscles of the upper half of the body, at least as far as the face. Most of the muscles of the neck are visibly atrophied, but the trapezius and sterno-mastoid are in good condition. The muscles are uniformly atrophied in the upper half of the body. On tapping the pectoral muscles over the ribs, local elevations occur. No fibrillary tremors are noticeable. There are irregular contractures of the hand and a striking appearance of the thumbs. The second phalanx is flexed, and the first drawn backward at a right angle. The muscles of the legs are atrophied to a less degree. Knee-jerk is exaggerated and ankle clonus marked, most on the left side. Faradic contractility is retained to a current of moderate strength. Partial degeneration reaction with galvanism is present.

CASE II. *Progressive muscular atrophy of traumatic origin.*—N. S., aged thirty-four, white, born in Germany, a sailor, during his infancy was sickly, but after the age of two years was strong and healthy. He denied any specific history. He had malarial fever in the summer of 1884, for three weeks, but recovered perfectly so far as he knows.

About three years ago while working in a rolling-mill, a ball of red-hot molten iron was dropped into water and exploded, and one of the fragments struck him in the right forearm, inflicting a severe wound; the bones were exposed and the tendons laid bare. The wound healed slowly, and he was under treatment for eleven weeks. His arm was not quite healed for nearly fifteen weeks, although he was able to do some work with it. He went back to the mill and for about six months his arm gave him no trouble, when he began to notice gradual wasting and loss of power in it, which slowly extended to the shoulder, the other arm, and later to the neck, etc., as now observed.

He presents advanced atrophy of the muscles of the forearm and shoulders of both sides. The muscles of

the neck generally are atrophied. When the patient bows his head, after reaching a certain point the head suddenly falls forward, and in lifting the head the muscles of the back and neck are brought into strained and unnatural action. He can only keep his head erect by resting the occiput on the back of his neck. The atrophy has not yet spread much over the lower half of his body.

He has fibrillary tremors, especially in the muscles of the chest and neck.

Both knee-jerks are exaggerated, and he has slight ankle-clonus. He complains of considerable pain in the legs and arms. His pupils are normal.

Farado-contractility is retained, partial degeneration reaction.

CASE III. *Diffused sclerosis, chiefly amyotrophic lateral, with bulbar paralysis.*—J. S., sixty-six years old, has been in the Philadelphia Hospital for many years. His mental powers are generally enfeebled, but his memory for past events is fairly good.

He has considerable tremor: his head sometimes shakes, and sometimes his trunk and entire body. Both hands are very much atrophied, the thenar and hypothenar eminences, interossei, etc., wasted. He has an apparent double wrist-drop. His fingers are usually a little flexed. He can elevate his arms but they are weak; the muscles high up in the limbs are slowly getting worse. The left upper extremity is weaker and more wasted than the right. While his hands have the appearance of double wrist-drop they are not completely helpless; he can with a strong effort extend his hands and fingers. The thumbs are usually carried across the palms.

Both legs are in a spastic condition, having a tendency to remain contractured in extension. The feet assume a slightly varus position. There is spasm of the adductors of the thighs. The muscles of the legs respond to faradism, but it requires a strong current, which is probably due to the condition of the skin. His senses of touch and pain are retained. He has incontinence of urine. Both knee-jerks are exaggerated, and muscle-jerks marked.

The right pupil is larger than the left. The iridic response to light is diminished. He has no true facial paralysis, but poor control of the musles of expression; he cannot with facility draw his mouth to one side or the other, and he has little power in the oral muscle, as in whistling. The general bulk of the tongue is small. The contours of the face are more strongly marked on the left side than on the right. He complains of difficulty in swallowing. Testing with water and bread, the difficulty seems to be in the constrictor muscles of the pharynx. His method of speaking is peculiar. He speaks with great effort, the difficulty being in phonation. as well as articulation. At times his speech is explosive or stormy in character; sometimes it is hesitating, but it is not distinctively of this character. Smell and taste are preserved.

Farado-contractility in the muscles of the forearm is retained. When a strong current is used on the extensor muscles of the forearm, while these contract the flexors contract so much more strongly that the movements of the extensors are obscured, an observation which would seem to show that when one group of muscles are much atrophied and weakened, extra-polar diffusion of the current to antagonistic muscles might lead to the mistake or supposing that the muscles tested did not respond.

CASE IV. *Unilateral atrophy of the tongue in an old man, with senile dementia.*—J. C., aged eighty-six, a laborer, had an insane grandfather; has had acute rheumatism, and malarial fever, has been a moderate drinker, but denies venereal disease. For several months he has suffered from incontinence of urine and feces, and has had some trouble in micturition.

He has a peculiar defect of speech; when he talks his articulation is a little indistinct and tremulous. His tongue is distinctly atrophied on the left side. The imperfection of speech appears to be due to this lingual atrophy, and weakness of the oral muscles. He has some tremor of both hands and arms. He appears to be weak on the left side, but there is no well-defined paralysis. He is irascible and irritable, and it is hard to fix his attention. At times his mind seems to wander, and he is often querulous and worrying. The arcus senilis is highly marked, and his bloodvessels are extremely atheromatous.

CASE V. *An irregular form of sclerosis with hemiatrophy of the tongue.*—J. W. J., thirty-six years old. About sixteen years before coming under observation had a chancre, and since then has had various attacks of sore throat. Ten years ago he first noticed slight numbness in the left foot beginning in the toes. This feeling extended slowly so that the entire left side of the body became weak in about two years. He retained power, however, on that side for nearly three years, when the left arm began to fail. He began to lose power in the right leg about three years after the first attack of numbness in the left foot. In about two years later he became almost helpless in the right leg. The right arm has not been affected. He began at a date he could not fix to have tremor of the tongue, which wasted on one side. His bladder has never been affected, except that he has sometimes suffered pain during micturition. For nearly two years he was so helpless that he could not leave the house. Under specific treatment he got well enough to go out, and for five or six years has kept about the same.

Examination shows no headache. He has abundant secretion of saliva, and has fair control over the facial muscles.

The right half of his tongue is practically normal. The left half presents a remarkable appearance; it is much smaller than the right, and is irregularly atrophied, so that its border presents an unevenly eroded, or corrugated look. It is in constant tremulous motion.

The left hand always feels cold to the touch, but has a flushed appearance. Sensation in the right leg and both arms is well preserved for touch, pain, and temperature. The left hand is numb and sensation is diminished. Sensation in the face is preserved. The left knee-jerk is exaggerated; the right well-marked; ankle clonus is decided on the left, slight on the right; muscle-jerk is decided on the left. He walks with a cane, dragging the right leg.

Both faradic and galvanic contractility are retained. At times he complains of dizziness. When he lies down in any position but upon the right side, he feels as if he would fall face forward.

CASE VI. *Simple muscular atrophy associated with old joint disease.*—W. C., aged thirty-two, white, is very

pale and emaciated. Atrophy of his legs is especially marked, in the right leg and thigh more than the left. Foot-drop is marked on the right side. Patellar reflex is retained in both legs, and about normal; ankle clonus is absent. The legs seem stiff and the patient cannot move either of them. He is totally unable to walk or stand. The paralysis of the right leg is more complete than the left. He does not appear to be able to move leg, foot, or toe. His right leg is extremely atrophied or emaciated from the hip down. The right hip-joint shows signs of old inflammation with adhesions, and other secondary changes, so that the thigh is absolutely immovably fixed to the pelvis. On handling the hip-joint no pain is experienced. The left leg is thin, but shows much less wasting than the right. The middle of the right thigh measures 11½ inches; of left thigh, 13⅛ inches; middle of right leg, 8½ inches; of left leg, 9¼ inches. The right leg from the anterior superior spinous process to the internal malleolus measures 28½ inches; the left leg, 32½ inches. Sensation appears to be perfect. Faradocontractility and galvano-contractility are normal.

CASE VII. *Idiopathic muscular atrophy.*—D. S., aged thirty-one, white, born in Pennsylvania, is one of twelve children, six of whom died of convulsions. One sister is hysterical, and all of the others are subject to fits. The patient has two older brothers, aged respectively forty and forty-two years, affected like himself. The disease came on them in childhood, as in his own case. He had spasms from infancy until he was twelve years old.

At eight years of age it was noticed that he could not go up stairs without putting his hands on his knees. He continued slowly to get worse, soon walking with a cane. He learned barbering at sixteen, and was able to work at it for ten years. At twenty-three he had to use crutches. Until 1882 the weakness was confined to the legs; it then began to involve the arms, which pained him when he raised them to shave.

He has no difficulty in speech or swallowing. His sight is good. The face shows very slight smoothing out, and weakness of the right side. The irides respond to light.

He exhibits universal, or almost universal, wasting, although in varying degree, of the muscles below the head. His upper extremities are very thin, particularly the upper arm and forearm. His hands are also wasted, but the thenar and hypothenar eminences and interossei muscles are not so much wasted comparatively, considering the stage of the affection, as the muscles of the forearms, hands, and trunk. The deltoid muscles are also not absolutely wasted. The left deltoid is less wasted than the right. Marked atrophy of the trunk muscles is well shown when he attempts any movements of the trunk, for which he is incapacitated except to a small degree. The latissimus dorsi and the pectorals are in an advanced stage of atrophy. The muscles of the lower extremities show wasting as above—the right muscles probably in the most advanced stages. The patient thinks his disease began in the thighs. In the lower extremities are well-marked vaso-motor changes. The feet and legs are purple or reddish in color, and colder than they should be, this mottling being most marked in the region of the knees and thighs.

The knee-jerk and muscle-jerk are abolished. Faradic and galvanic contractility are retained.

Sitting, this patient can, by an effort of the will, cause the muscles of the thigh to contract almost like fibrillary or involuntary contractions, and yet he cannot use the same muscles for their usual physiological purposes. He cannot, for example, kick out, or cross the legs, and yet he can produce by a willed effort waves of muscular movement in the quadriceps and other muscles.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 20, 1888.

THE PRESIDENT, A. JACOBI, M.D., IN THE CHAIR.

DR. THOMAS E. SATTERTHWAITE read a paper on

A NEW STUDY OF LOBAR PNEUMONIA; WITH STATISTICS DERIVED FROM A REVIEW OF FIFTY-SIX FATAL CASES.

(See page 1.)

DR. ANDREW H. SMITH said that the subject was one beset with difficulties, whether viewed from one point or another. There was one fact in the history of pneumonia which might have some bearing upon our ideas of its nature. He referred to the very peculiar temperature which was really characteristic of the disease. It reached very early an exceedingly high point, maintained it for a considerable length of time, and then abruptly fell. The fall, which took place about the sixth day, was not only to normal, but frequently to a subnormal degree; yet there was not a corresponding change in the physical signs to give any explanation. This would seem to indicate that there was something in the disease entirely different from an ordinary inflammation. The measure of inflammation, so far as concerned the physical signs, were the same. It was quite possible that the production of poisons in the blood had something to do with this change. It would lead one to suspect that the disease was due to a germ of some kind.

The disease differed from any other in another respect, which might have some bearing on the treatment. He referred to the peculiarity in the disturbance of the circulation. This disturbance was mostly in the lungs, and as a result of the obstruction to the flow of blood through the lungs, there was accumulation of blood on the venous side and paucity on the arterial side of the circulatory system. The labor thrown on the two sides of the heart was thus made very unequal, the right heart being burdened while the left had less than what it was accustomed to do. The heart stimulants would generally affect the right side no more than the left, and some were largely useful in other affections by their influence on the vasomotor system, but it had been shown that there were no vasomotor nerves connected with the pulmonary vessels.

It seemed to Dr. Smith somewhat difficult to frame a rational basis of treatment in these cases. The fact that there had been advocates of a great many different forms of treatment, and the efficiency of the same methods had varied at different times in the same hands, would seem to show that no very clear indications, which were not general, existed. Certainly, when there existed what had been called collateral fluxion, the temptation was strong to withdraw some blood, and it had been found that venesection was followed promptly by a certain amount of relief. Yet the relief could be only tempo-

rary, while if the procedure were repeated the patient would necessarily grow weaker.

The tendency to death was not due to congestion of the lung, but to heart failure, particularly of the right side. Then there was the high temperature, and also the poisonous effect upon the brain and nervous system, which constituted indications for treatment. He was fully in accord with the author that antipyretics which had a depressant effect should be avoided. While he thought the existence of a high temperature in itself would be injurious, yet he disapproved of reducing it by a means which might have a worse effect than the temperature itself would have exerted. It were better to do too little than to do too much. To promote the elimination of excrementitious material, the bowels and kidneys might be made active. The skin was likely to be active without the use of diaphoretics. He was not at all surprised that the expectant method had so many advocates, nor at its comparatively good results.

There was one remedy which remained to be mentioned as being of decided advantage in a very limited number of cases. It was the inhalation of oxygen gas. Ordinarily the blood would not take up much more oxygen than it obtained from ordinary atmosphere, but there were times in pneumonic cases when that little would bridge over an imminent danger, especially when there was a large amount of fluid in the other lung. It certainly reduced the labor of respiration to some extent. The heart's action should be supported in every way. The question of how much alcoholic spirits should be administered was difficult to determine, but he believed they were too freely used by some. When the blood was loaded with alcohol it became a direct irritant to the heart itself.

DR. BEVERLEY ROBINSON felt less well satisfied on a few points in connection with pneumonia than did Dr. Satterthwaite. For instance, he had never seen the characteristic sputum in any other disease, and he thought that in the rusty sputum of the stage of hepatization we had a sure diagnostic sign. With regard to causation, without attempting to pass as far as the precise cause, he thought great bodily fatigue and foul air were efficient factors. The disease also often developed suddenly in persons returning from the theatre after having overworked mentally during the day. Regarding treatment, those who had had experience a few years ago might find the same remedies of much less value to-day. The types of the disease changed, and required a change of treatment. He disapproved of the use of antipyretics which weakened the heart and general system in this disease, or any other where in this way they might exert an injurious influence. He could not help believe that high temperature, after all, was only a symptom, and a single symptom of a grave disorder, and it had always seemed unreasonable to him to reduce the temperature by a remedy which would depress an already weakened system. Digitalis in infusion could be used with far greater safety than newer antipyretics, or aconite, or veratrum viride.

He was surprised that Dr. Smith had come to regard oxygen gas of use in only so limited a field. In the treatment of pneumonia he employed oxygen gas, gave the patient black coffee, pretty free use of brandy in milk or brandy alone, small doses of calomel, the judicious use from time to time of some cardiac tonic, as digitalis, or strophanthus; avoid drafts. He deplored the use of the oiled jacket which made drafts all the more dangerous.

DR. SIMON BARUCH said that his interest in the subject centred principally in the treatment. He had dropped heroic measures as they were taught when he was a student, and had gradually adopted the expectant plan of treatment. He had read a paper, many years ago, before the South Carolina Medical Society, in which he drew some lessons regarding the treatment of pneumonia from the homœopaths. He meant the original homœopaths who treated disease by infinitesimal doses, or, as we knew, who did not treat them at all medicinally. Their careful attention to diet and hygienic management accounted for their success. There was no remedy which had any influence in checking the disease, but there were remedies which modified its course considerably. Regarding the high temperature, it was not an indication of the dangerous character of the disease. While he might not have the antipathy for modern antipyretics used in other diseases which Dr. Robinson had shown, yet he considered their depressant action injurious in pneumonia; nor did he use quinine.

The proper way to stimulate the right side of the heart was to relieve it of the load bearing upon it by influencing portal circulation. He gave eight to ten grains of calomel, and, if necessary, followed it by a saline cathartic. It might be necessary to use digitalis. He did not believe the types of the disease changed with the season or year, but that they did change according to whether one at one time had a hospital practice and at another private practice, etc. The original condition of the patient altered the type. He did not share Dr. Robinson's objections to the cotton jacket and oiled silk. He employed non-absorbent cotton, and with the oiled jacket outside to prevent evaporation and keep the surface warm, the perspiration bathed the body, and acted as a good substitute for a poultice.

DR. ROBINSON disapproved of a poultice, and of the use of cotton unless changed often enough to leave the body constantly dry.

DR. SATTERTHWAITE reviewed some parts of his paper regarding the characteristic sputa of pneumonia, and emphasized the fact, when speaking against depressing antipyretics, that high temperature in itself was not an indication of the dangerous character of the disease. It pleased him to know that the members were so favorable to the expectant treatment.

SECTION ON THEORY AND PRACTICE OF MEDICINE.

Stated Meeting, December 18, 1888.

R. C. M. PAGE, M.D., CHAIRMAN.

DR. E. D. FISHER read a paper on

CEREBRAL SYPHILIS.

Rumpf had divided, he said, the disease in the brain into three classes: (1) disease involving the skull; (2) new growths involving the brain or its membranes; (3) specific disease of the cerebral vessels. It was to the latter that the paper was more particularly designed to call attention.

As to the pathology, many of the earlier appearances in cerebral syphilis, in the second stage, were probably due to simple hypertrophy of the tissues affected. It was cer-

tainly time, however, that in the tertiary stage, whether occurring early or late, the tissue-changes, whether in the form of a gumma or merely affecting the arteries, had a specific character. Hence he believed with Rumpf that the virus itself was still active, and that these changes are not due to the effect of a poison which had expended itself but left its impress on the system. Also to sustain this clinically, he felt sure that there were found many cases transmitting syphilis late in the course of the disease which then passed through the same class of symptoms as when the disease was transmitted early in its course.

Meyer considered as almost pathognomonic of syphilis a matting together of the dura and pia with softening of the cortex, since in pachymeningitis from other causes this rarely occurred. Characteristic of the pathological changes of syphilis, as distinguished from atheroma, according to Heubner, was the fact that the larger arteries were alone affected in atheroma and that continuous tracts were involved; while occlusion occurred by thrombosis, and never by a narrowing of the lumen of the artery. The process consisted of a simple hypertrophy, resulting in calcification; there being no new growth. In syphilis, both large and small arteries were affected; the tendency being, however, toward the small and middle sized vessels. We might, indeed, have thrombosis; but the marked lession was narrowing and final occlusion of the vessels from the extension of the new growth internally, though rarely in the endothelial lining. The process was rapid, and differed from atheroma in that it was not continuous, but occurred in plaques. Arterial disease might occur entirely independent of gummata, and according to Dunn the vessels of the pia were very frequently involved; leading to softening and atrophy of the cortex. The tendency to the formation of new vessels with their walls so characteristic of all granular tissue was here present; so that we had at first a tissue richly supplied with vessels.

Rumpf placed the origin of the arteritis in the middle coat of the arteries, and insisted on its character of granular tissue, similar to that found in all syphilitic growths. He admitted the difficulty of differentiation microscopically from atheromatous arterial changes, but believed a special bacillus could here be found which was the source for the primary chancre and the late growth. A drawing of his representing syphilitic arteritis, in which the narrowing of the lumen was clearly delineated, corresponded very closely to a microscopical section of the basilar artery in a case of Dr. Fisher's, which he related at the close of the paper.

In treating of the symptoms of cerebral syphilis, he referred first to the psychical changes often present. While occasionally sudden in their onset, they were more often gradual, extending over months or even years. We noticed a general loss of mental power, the ethical nature seemed to suffer, the memory became weakened, and there was often a feeling of loss of power of performance. Insomnia, independent of cephalalgia, was one of the early symptoms, and always a serious one. It sometimes had associated with it somnolence or even stupor. Headache was, perhaps, one of the most frequent of all the early symptoms. It was, however, always indicative, if localized, of either cranial bone or dura affection. It was very often absent when the lesion was situated in the arteries. The cranial nerves, and especially the third, fifth, and sixth pairs, were early affected, either partially or completely. Hutchinson said that he had never seen the seventh alone affected, although such cases have been reported. He was equally strenuous on the diagnostic value of affections of the fifth as indicating syphilis.

In arterial disease unassociated with meningitis or tumor we often found the single paralysis of the cranial nerves. Epileptic seizures are often present, and as the inflammation was usually diffused rather than circumscribed, they were more often general than localized. As regards the eyes, Dr. Fisher called attention to choroiditis and retinitis as indicative of an already existing affection of the cerebral vessels. A cloudiness of the disk, appearances of atrophied spots in the fundus, traces of a past retinitis or choroiditis, and gummatous enlargements especially involving the terminal arteries, naturally aided in a positive diagnosis. As a diagnostic point, any interference with vision in a part of the field of vision or a general loss of acuity of vision in the young should lead to the suspicion of syphilitic disease of the cerebral arteries.

Paralysis of parts widely separated was strongly diagnostic of syphilis. Also hemiplegias coming on without loss of consciousness in which the paralysis was preceded by numbness and tingling, and gradually extended from the arm to the leg (especially if there had been previous irritability for weeks or months, loss of memory, and perhaps headache, confusion of ideas, and somnolence or insomnia), occurring in persons under forty years of age, were probably specific.

DR. WILLIAM H. THOMSON considered the paper a valuable contribution to a subject of great interest and very great obscurity. The differential diagnosis of the various forms of cerebral syphilis, he said, is often a very difficult matter. In the first place, the question arose, Have we syphilis at all to deal with? The nervous symptoms alone are not sufficient to determine this point, and it is necessary, therefore, to make an examination over the body of the patient. There is one mark which he regards as of considerable importance in this connection, namely, tenderness on pressure at the junction of the sternum with the ensiform cartilage. It is almost uniformly present in syphilitic patients, and its diagnostic value is, therefore, very great. It being reasonably sure that the patient is suffering from cerebral syphilis, it must then be determined whether he has meningeal trouble, syphilitic tumor, or vascular disease. If the latter, we should endeavor to find out what particular form of vascular syphilis is present.

Syphilis is to be suspected in any case which is characterized by variableness and inconsistency, in which it differs from other forms of disease. In meningitis headache is the most marked characteristic. In the second place, we have the gradual development of the symptoms. Thirdly, we should examine the condition of the vessels generally, and see whether they are soft and natural. In syphilitic tumor we have to rely very much upon the condition of the eye; and choroiditis is much more commonly present than retinitis. Sluggishness of the pupil, which has been referred to in this paper, he has often noticed, though he had not been aware of its diagnostic significance; and he said he was very glad to have his attention called to this point. Sometimes with meningitis or tumor there are symptoms of insanity and epileptiform seizures.

About a year ago he had been called in consultation in the case of a lady well advanced in years, who was in a comatose condition. There was no evidence of kidney disease, indicating that the trouble was uræmic, and pressure upon the sternum elicited groans from the patient, notwithstanding the coma. Suspecting, therefore, that the trouble was due to cerebral syphilis, he advised specific treatment, and the patient afterward recovered. Yesterday he said he was called to see the husband of this lady, a man seventy years of age. About two weeks ago he began to be affected with confusion of speech, great irritability, and motor symptoms. These motor symptoms were not of a paralytic kind, but referable to incoördination. Depression alternated with excitement, and he had become quite emotional. He also had insomnia at night, and suffered from somnolence in the daytime. Dr. Thomson said he had very little doubt that this patient was suffering from syphilitic endarteritis.

DR. LANDON CARTER GRAY said that if we started from the prime anatomical lesion of syphilis, the round cell, we could get a better idea of syphilitic developments. It was a characteristic of the syphilitic round cell that it had an enormous vitality. It would live for a long time in the system, and would undergo retrograde metamorphosis without the formation of pus. As long as the cell caused no structural disease by its presence, the prognosis was favorable. We did not yet know all the forms of cerebral syphilis, but some of them were sufficiently familiar. There might be, in the first place, a chronic interstitial encephalitis, scarcely distinguishable from that of general paresis, except by its slower progress. Secondly, there was pseudo-encephalitis, in which there was great danger from sudden death. In other cases the disease attacked the arteries. Precisely what the lesion was he did not know, but there did not seem to him to be anything pathognomonic about the affection. Finally, there was an implication of the meninges: (1) of the dura, causing headache; (2) of the pia, involving the cortex.

In the majority of instances it was necessary to make the diagnosis from the conditions found in the brain, rather than from evidences of syphilis derived from other sources. Dr. Gray then proceeded to quote, from a paper which he read last year before the Philadelphia Neurological Society, and which had been published in THE MEDICAL NEWS, certain groups of symptoms which he had formulated from his own experience as indicative of specific infection.

DR. CHARLES L. DANA said that the symptomatology of cerebral syphilis was very difficult; but from the contributions that had of late years been made to the subject, we could now form a pretty correct picture of it. The pathology, however, still remained in a very unsatisfactory state. He could not believe that the lesions which are observed are due to Dr. Gray's round cell, since this anatomical factor was common to other conditions and affections. In the cases which he had seen, there were four different forms of lesions, which were as follows:

1. Local hyperæmia.
2. Local meningitis and gummatous changes.
3. Cranial root neuritis, or neuritis itself.
4. Degenerative changes resembling those from other causes.

DR. FISHER, in the course of his remarks in closing the discussion, said that he had found the tenderness of the sternum on pressure, as pointed out by Dr. Thomson, a valuable diagnostic sign of syphilis. As to the round cell referred to by Dr. Gray, he doubted whether it was of syphilitic origin, and thought that if there was anything specific about the pathology of the disease it was a bacillus.

OBITUARY.

EDWIN M. SNOW, M.D.,

died suddenly, of heart disease, at his home in Providence, R. I., on December 22d, in the sixty-ninth year of his age.

He was born in Pomfret, Vermont, and was a lineal descendant of William Snow, who was born in England, in 1624, emigrated to Plymouth, Mass., and afterward was among the early settlers of Duxbury and West Bridgewater, Mass. After preparatory studies at Kimball Union Academy and the New Hampton Institute, both in New Hampshire, Dr. Snow entered Brown University, where he graduated in 1845. Subsequently he studied medicine with Dr. W. D. Buck, at Manchester, N. H., and graduated at the College of Physicians and Surgeons, New York, in 1849. He began practice at Holyoke, Mass., the same year, and treated many cases of Asiatic cholera, which disease was then prevalent in that city. The next year he went to Providence to practise, and in 1854, in the capacity of dispensary physician, he was again called on to treat numerous cases of cholera, and became much interested in tracing the connection of the disease with local conditions of filth. In 1855 he was elected a member of the Common Council of Providence, and was also appointed City Registrar of Births, Marriages, and Deaths, when that office was first created; and also Health Physician and Health Officer at Quarantine. In 1856 he was elected to the newly established office of Superintendent of Health, and from that time until 1884 was annually reëlected to that position, and also as City Registrar, which latter office he continued to hold to the time of his decease.

He was appointed to superintend the census of Providence in 1855; was Superintendent of the State Census of Rhode Island in 1865 and in 1875, and was Supervisor for the District of Rhode Island in the National Census of 1880. In 1863 he was appointed Inspector of Hospitals by the United States Sanitary Commission, and spent several weeks in examining the military hospitals in Philadelphia and vicinity, and in visiting the Army of the Potomac, opposite Fredericksburg. He also took a prominent part in the meetings of the Quarantine and Sanitary Conventions, which first met in Philadelphia in 1857, and in the following years in New York, Baltimore, and Boston. He was a member of the National Prison Congress, which met in Cincinnati in 1870, and a delegate to the International Prison Congress, in London, in 1872. For several years he was an Inspector of the Rhode Island State Prison and Secretary of the State Board of Charities and Corrections.

Dr. Snow had been a Fellow of the Rhode Island Medical Society since 1850, and was President of the same for the year 1876–77. He was also a member of the Providence Medical Association, the American Medical Association, and the American Academy of Medi-

cine. He was a member of the consulting staff of the Rhode Island Hospital from the time of its establishment. In 1868 he was a State delegate to a convention in Springfield, Ill., in relation to the Texas cattle disease, and was Chairman of the Rhode Island Cattle Commission in 1871–72. From 1874 to 1878 he was Chairman of the State Commission which built the new State Prison in Cranston, R. I. He was sent as a delegate from the United States Government to the International Statistical Congress, which met in St. Petersburg in 1872. He was one of the original founders of the American Public Health Association, and was for two years Vice-President, and for one year President of the same. For twenty-five years he was a Trustee of the Providence Reform School, and in 1876 was elected a Trustee of Brown University. He was the author of numerous pamphlets and reports, among which are those on "Asiatic Cholera," "Smallpox," and various municipal and sanitary subjects; twenty-four Annual Reports as City Registrar, and eight Annual State Reports in Registration.

In politics Dr. Snow was a Republican, in religion a Baptist. He was widely known for his extensive and pre-eminent knowledge of the subjects of statistics, registration, and sanitation. He was a kind and genial man—held in the highest esteem by his fellow-citizens, while the intelligence, honesty, and carefulness with which he fulfilled the duties of his many positions of public trust justly enrolled him among the most honored officials of the city and State.

NEWS ITEMS.

The Abuse of Charity.—According to the *Physician and Surgeon*, December, 1888, out of sixty cases of senile cataract operated upon in one year in the Ann Arbor clinic, ninety per cent. were eminently able to have paid the fee of a specialist for a private operation. In one week among the cataract patients who were operated upon, an investigation showed that there were four patients the poorest of whom was worth over fifteen thousand dollars, one estimated his wealth at forty thousand, another had given the bulk of his property to his children, but retained two hundred acres of cultivated land, well improved and completely stocked, while the fourth was worth over three hundred thousand dollars. The fourth, or richest of these, was not a resident of the State of Michigan.

Nickel Vessels.—Although the opinion of physicians and physiologists often varies as concerns the toxic effects of copper salts, it is generally considered that the use of copper vessels in culinary operations is detrimental to health, and nickel has been much praised as a substitute for copper. DRS. LABORDE and RICHE, after many physiological experiments, have come to the conclusion that nickel salts must be absorbed in considerable quantity before becoming obnoxious, and that the use of nickel vessels in culinary or pharmaceutical operations is without the slightest danger to health.—*Popular Science News.*

NOTES AND QUERIES.

THE ORIGIN OF THE LATE YELLOW FEVER EPIDEMIC.

To the Editor of THE MEDICAL NEWS,

SIR: As the widow of the late Charles M. Turk, and in defence of his honor, and in justice to our child, I desire to correct an error and misrepresentation of Surgeon-General Hamilton, occurring in an address reported by you in your issue of the tenth of November last, with relation to the yellow fever and the part my husband (he was the only person of the name here) is alleged to have taken in introducing the disease in Tampa.

The language made use of is, "an Italian by the name of Turk." With reference to this I have to say, that Mr. Turk was an American, a native of the State of Ohio. I am a native of the State of Florida, and had been married to him, at the time of his death, which occurred on the 22d September, 1887, about eighteen months and during all that time lived with him at Tampa. The further, language used is, for this purpose (smuggling) "the man Turk and his assistant, Pete, made frequent surreptitious visits to Key West." This statement is utterly false. I deny, and it can be readily otherwise proved, that Turk never, during the time of his marriage with me, was absent from home but on three occasions: once at Jacksonville, once at Orlando, Fla., when I accompanied him, and on a third occasion he was out on a hunting expedition a few days before his death, when he slept out, camping in the open air but two nights. He (Turk) had nothing to do with a man named Pete, but he was accompanied on the hunting expedition by an Italian named Pepe, and I herewith enclose an affidavit of a friend and intimate companion of Pepe, to show that he never was in Key West.

I do not know where Surgeon-General Hamilton got his information, but if the remainder of his address is based on no better information than that relating to my husband, his statement is entitled to no respect whatever.

He further goes on to state that the whole family of Turk was the first to be taken sick. This, again, is utterly false. Turk and myself were living, at the time of his death, with my mother, brother, and sisters. We had all just been burned out at Tampa, and none of us took the fever from my husband. The absurdity of the affair was that the house and premises of my brother-in-law, C. W. Wells, near where we lived, were quarantined, while that in which we lived was not so treated. Mr. Wells and family also escaped at that time, though some two months afterward they were attacked and were slightly sick.

I regret that this statement is so tardy, and trust that you will do me the justice of publishing it.

MARGARET TURK.

"State of Florida,
"County of Hillsborough.

"On this 26th day of December, A.D., 1888, personally appeared before me A. Bartholomew Philogamo, to me well known, who, being duly sworn, deposes and says:

"I am well acquainted with Vincenzo Pepe, and lived with him and occupied the same apartments, and was in daily communication with him for some months prior and up to the death of Charles M. Turk, which occurred on or about the 22d day of September, 1887, and I know that he, the said Pepe (I do not know any Italian in Tampa going by the name of Pete), during that time, never went to Key West, or was absent from Tampa for more than one night at a time, but on one occasion, and then I understood he accompanied Charles M. Turk on a hunting expedition. I also know that said Pepe had not, during the time he was in Tampa, and he left there on 3d October, 1887, the yellow fever.

"A. B. PHILOGAMO.

"Sworn before me, at the city of Tampa, Florida, on the day above written.

[SEAL] "FRED. J. LAPENOTIERE,
"*Notary Public*,
"State of Florida."

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LIV. SATURDAY, JANUARY 12, 1889. NO. 2.

ORIGINAL ARTICLES.

TUMORS OF THE BRAIN IN CHILDHOOD.

Their Variety and Situation, with Special Reference to their Treatment by Surgical Interference.[1]

BY M. ALLEN STARR, M.D., PH.D,

CLINICAL PROFESSOR OF DISEASES OF THE MIND AND NERVOUS SYSTEM IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

UNTIL a recent date the subject of intracranial tumors in childhood has appeared to be one of so little practical importance that it has received but little attention. The interest in a case of tumor of the brain appeared to end with the diagnosis, and there was no class of cases which presented a more hopeless prognosis. Medical treatment was admitted to be useless, and surgical interference was not supposed to be possible.

But the very remarkable advances of recent years in the knowledge of the localization of cerebral functions has made it possible to diagnosticate the existence and the location of cerebral tumor with much greater accuracy than formerly. And the equally marvellous achievements of cerebral surgery offer a hope of the possibility of treatment. It seems, therefore, that any study of cerebral tumors at present is not ill-timed, and since no article upon this subject has been published, excepting the chapter by Steffan, in Gerhardt's *Handbuch der Kinderkrankheiten*, written eight years ago, it has occurred to me that a presentation of the subject as relating to children would prove both interesting and profitable.

All authorities upon brain tumor agree that it is a disease which is equally frequent at all ages. Gowers, indeed, states that one-third of all the cases occur in persons below the age of twenty. And a study of the three hundred cases which form the basis of this article shows that infants, children, and youth are about equally liable to develop tumor within the cranium. Males are more liable than females in the proportion of about three to two. It is evident, therefore, that those who see much of children's diseases are almost as likely to meet with cases of tumor of the brain as are general practitioners. In the list of organic nervous diseases of childhood, cerebral tumors stand high, being only exceeded in frequency by meningitis, spinal paralysis, and cerebral hemorrhage.

[1] Read before the Section on Pædiatrics, New York Academy of Medicine, November 28, 1888.

Such being the importance of this subject, a careful study of it seems necessary. As a basis for such a study I have collected three hundred cases of cerebral tumor occurring in persons below the age of nineteen. It is true that individuals between fifteen and nineteen can hardly be called children, but, as a matter of fact, cerebral tumor is a slowly progressing disease, and it had, in the majority of the cases collected, developed from two to ten years before death. It seemed, therefore, necessary to include all cases which had terminated prior to the age of nineteen.

These cases have been derived from numerous sources, and inasmuch as collections of cases made by different authors often include the same cases, I may state that there are no duplicates in this collection. About one hundred of these cases have been taken from Bernhardt's collection of brain tumors, published in 1881. About ninety of them were found in Steffan's article, already mentioned, published in 1880. The remainder have been brought together from the medical journals published since 1880; and I may say that the majority of the German, French, English, and American periodicals have been carefully searched and all the cases in them tabulated.

Table I. shows the variety of tumors found, the situation occupied by each variety, and the proportion of tumors of each variety in each location; and it affords data for a discussion of the possibility of surgical interference.

I. *The variety of tumors* found in children is great, but the overwhelming frequency of tubercular tumors is at once evident (over one-half of the entire number), and also the great rarity of carcinoma and gumma in childhood. This latter point is of interest, for a somewhat similar table of tumors in adults would show that above the age of nineteen gumma is much more frequent than any other form of tumor. It is also to be noticed that tubercular tumors are not infrequently multiple, a fact which should not be forgotten in making a diagnosis of the seat of the disease.

Glioma and sarcoma follow tubercle in frequency and make up about one-tenth of the cases each. Cysts of the brain may arise either in connection with sarcomata or independently, as the result of parasitic infection. Hydatid cysts, echinococcus, and cysticercus are very much more frequently met

TABLE I.—BRAIN TUMORS IN CHILDHOOD AND YOUTH.

with in the German records than in English or American journals. Kuchenmeister, in an article on this subject, has collected eighty-eight cases, but I have not included them in the table, as they would give an appearance of undue frequency of this disease, which would mislead. In America a cerebral cyst of parasitic origin is a curiosity, and but few cases are to be found in our journals. Carcinoma of the brain alone is a great rarity, and among the cases tabulated are four which invaded the brain secondarily, after beginning in the retina of one eye, a not infrequent form of the disease in childhood.

In comparing this list of the relative frequency of the various forms of tumors with smaller lists, I find that the relative frequency is about the same in all lists; and, therefore, I think that this may be considered fairly reliable, though statistics are always to be looked at with care.

The diagnosis of the kind of tumor present is always a matter of probability in any case; and, hence, such a list has a certain diagnostic value. It will, of course, occur to any one in the presence of a child with brain tumor to inquire carefully into any history of hereditary tendency to tubercular disease, and to examine carefully for other evidence of tuberculosis, such as enlarged glands, scrofulous joint disease or phthisis, chronic diarrhœa, etc. Occasionally the tubercular tumor has been found, after death, to be the only manifestation of infection, but this is not the rule. Tubercular tumors are so frequently multiple that the occurrence of local symptoms pointing to more than one tumor will also point to tubercular tumors.

The determination of the question as to the existence of tubercular disease is of the greatest importance, in view of the possibility of surgical interference. Supposing that a brain tumor is diagnosticated, and is located in a place accessible by trephining: if it is thought to be tubercular is an operation justifiable? Such an operation may prolong life, but the disease may reappear in the brain or elsewhere. The operation is certainly attended by greater danger than in a non-tubercular person. Yet the existence of tuberculosis does not prevent the surgeon from attacking tubercular joints or tubercular testicle. Should it prevent his attacking a brain tumor? Von Bergmann[1] thinks that it should, affirming that it is impossible to remove the cheesy masses from the soft brain coverings and tissue with the thoroughness that is possible in dealing with bones. He claims that the operation will be incomplete, and that a relapse in then certain. English surgeons have taken a different view, and have removed successfully several tubercular tumors completely without relapse. But further experience is certainly necessary before any rule can be laid down in the matter. The greatest drawback met with in dealing with tubercular tumors by surgical measures is the possibility of the presence of more than one tumor, the failure to detect and remove more than one, and the consequent need of a second operation when the second tumor develops sufficiently to give rise to special symptoms.

If there is no probability in a case of tumor that tubercular disease is present, the diagnosis of the kind of tumor present is difficult. Gumma is so very rare that unless a distinct history of acquired syphilis with other syphilitic manifestations, and the occurrence of nocturnal headache and insomnia are present, it may be dismissed as a most unlikely form of disease. Carcinoma of the brain, though in a few cases primary, is usually secondary to carcinoma elsewhere. Should such a tumor be found in the body, especially if it should be found in the orbit and in connection with the retina, the diagnosis of the cerebral tumor can be made. Otherwise, it cannot be thought probable. To remove a secondary cancer in the brain when the primary cancer remained would hardly be undertaken by any good surgeon.

Cysts in the brain of parasitic origin form very slowly, never destroy but always displace the brain tissue, and rarely, if ever, give rise to localized symptoms. In a case of brain tumor in which the

[1] Chirurg. Behandl. d. Hirnkrankheiten, p. 58.

symptoms are all general and not local the possibility of cyst should not be overlooked, and the child's history should be investigated in regard to any exposure to infection, the presence of tapeworm or of hydatid tumors elsewhere. There is no reason why such cysts should not be removed.

The remaining varieties of tumor—glioma, sarcoma, or gliosarcoma—cannot be absolutely differentiated from each other. Occasionally sarcomata in other regions of the body may lead to the suspicion that there is one in the brain, but in the thirty-four cases here brought together, there was a sarcoma elsewhere than in the brain, in only four. Hence, this point of diagnosis is not to be relied upon. Glioma and sarcoma may be equally slow in growth, may produce very marked symptoms or none at all, and do not differ markedly in their selection of situations in which to develop. Bramwell believes that glioma starts in the white matter and invades the gray matter. Ziegler affirms the contrary, and certainly the cases here cited confirm the statement of the German pathologist; but from a disputed pathological question no diagnostic conclusions can be drawn. Nor does the mode of origin throw any light upon the differentiation of sarcoma and glioma, for both result from blows and falls upon the head with equal frequency.

There is but one fact which may make a differentiation possible, viz.: that glioma is usually very vascular, much more so than any other tumor. A tumor which is vascular varies very much in its size, being, as it were, erectile. Variations in size within the brain are impossible, but the corresponding condition to erection in such tumors is an increase of intracranial pressure. Variations of intracranial pressure manifest themselves, subjectively, by varying intensity of symptoms, and by the possibility of modifying symptoms by means of agents which affect the blood pressure, and objectively by the state of venous congestion of the retina. Furthermore, in glioma, hemorrhages within or near the tumor sometimes occur, giving rise to symptoms of apoplexy. Therefore, in a case of tumor, great and sudden changes of intensity in the symptoms, accompanied by visible changes of circulation in the retina, and affected in one way or another by such measures as hot baths, cold douches to the spine, hot mustard baths to the feet, or free watery purgation will indicate a vascular tumor, probably a glioma. And this diagnosis will be reinforced by the occurrence of attacks apoplectic in character in the course of the case. See Case 42, Table II. And yet there are cases of glioma in which the tumor is quite hard and encapsulated, and in which these symptoms will be wanting.

But there is a practical application of these points of diagnosis regarding the vascularity of the tumor in view of surgical interference. The form of tumor most suitable for removal is the hard, encapsulated, non-vascular tumor. That is the usual form of sarcoma, and is occasionally the form of gliosarcoma and glioma. A case, therefore, is much more suitable for operation in which no vascular symptoms, such as those mentioned, are present, whether it be sarcoma or glioma. And, *vice versa*, a tumor showing marked vascular symptoms will not be a favorable one for operation, no matter what its variety or position.

II. Passing now from the consideration of the varieties of brain tumor and their differentiation, let us look at *the situation of the tumor*.

It is evident from Table II. that all parts of the brain may be invaded by tumor, but that certain parts are invaded with special frequency in childhood. These parts are the cerebral axis and the cerebellum. By the cerebral axis is meant that part of the brain which includes the basal ganglia and internal capsule; the corpora quadrigemina and crura cerebri; the pons and the medulla oblongata;[1] and which lies upon the cranial floor and is therefore invaded by tumors lying upon the base of the brain. Of the tumors collected, about one-third were in the cerebral axis. The diagnosis of such tumors is not difficult, as they usually give rise to very numerous local symptoms. It is not my purpose to discuss these here: they may be found in all the recent articles upon the local diagnosis of cerebral disease. The point of interest is that no case of tumor of the cerebral axis can be reached by the surgeon. The situation of the parts is such that a tumor in them is not near enough to the convex surface of the skull to be accessible. And, therefore, in estimating the number of the cerebral tumors in this collection which might have been the subject of surgical treatment, this class, constituting one-third of the number, must be at once excluded.

Coming next to tumors of the cerebellum we find that they number 96. They are much more common in children than in adults. Thus, in a collection of American cases of cerebral tumor without regard to age, which I have made, I find that of 45 cortical tumors 3 occurred below the age of nineteen, while of 29 cerebellar tumors 11 occurred below the age of nineteen: or, to put it more clearly, fifteen cortical tumors occur in adults for every one in a child, while only two cerebellar tumors occur in adults for every one in a child. It is, therefore, evident that children are especially liable to develop cerebellar tumors.

The diagnosis of cerebellar tumor is not difficult. The general symptoms of brain tumor are fully and rapidly developed, viz.: headache; mental disturbance, irritability, and apathy; vertigo; vomiting; optic neuritis, with or without blindness, and possi-

[1] The cerebral axis is represented by Fig. 376 in Quain's Anatomy, vol. ii., eighth edition.

TABLE II.—CASES OF CORTICAL AND SUBCORTICAL TUMORS.

No.	Author; reference.	Sex, age.	Variety and position of tumor.	General symptoms.	Local symptoms	Remarks.
1	Steiner, in Bernhardt, Beiträge zur Sympt. u. Diag. d. Hirngeschwülste, p. 105.	M. 3	Tubercular tumor, size of hen's egg, in anterior part of right hemisphere.	None.	None.	Tuberculosis of lungs and glands. Diagnosis and operation impossible.
2	Bettelheim, in Bernhardt, l. c. p. 103.	M. 13	Large ecchinococcus cyst in left frontal lobe near its apex.	Headache; optic neuritis; vomiting; sopor; slow pulse.	Prominence of eyeballs; impaired memory; right hemispasms with hemiplegia and weakness of legs.	Diagnosis possible if the onset of the spasms and paralysis was gradual and progressive. Operation impossible.
3	Petrina, in Mills, Pepper's Syst. Med., v.p.1069.	M. 16	Glioma within both frontal lobes extending to base and elevating the corp. callos.	Frontal headache; optic neuritis; vomiting; mental failure; slow pulse.	Irritability and weakness of mind, with erratic conduct; impaired vesical control; choreic and automatic movements of right arm, with tremor.	Diagnosis and operation impossible.
4	Henoch, in Bernhardt, l. c. p. 73.	F. 3	Tubercle, size of pigeon's egg, on cortex of posterior part of right frontal lobe.	Convulsions; somnolence.	Left hemiplegia, with contractures.	Diagnosis and operation impossible.
5	Archer, in Bernhardt, l. c. p. 73.	F. 11	Tubercle in first and second left frontal gyri reaching the cortex.	Headache; convulsions; stupidity.	None.	Hip-joint disease. Diagnosis impossible; operation possible.
6	Neureutter, in Steffan, Handbuch der Kinderkr. art. Geschwülste, Bd. v. p. 631.	F. 3	Tubercle, size of bean in left frontal lobe; another in cerebellar cortex; tubercular meningitis of base.	Occipital headache; insomnia; convulsions at first general, later local spasms; spastic contractions; marasmus.	Spasms in left limbs, then contracture of left wrist and neck; later extension of left leg; opisthotonus; trismus.	Rachitis. Diagnosis of position impossible; operation impossible and useless.
7	Mills, Jour. Ment. and Nerv. Dis., 1887, p. 707.	M. 16	Reddish-gray tumor 3 x 2½ x 2½ inches, involved the second frontal gyrus and parts of adjacent gyri, and invaded the white matter without reaching the corp. striatum on the right side.	After blow on head convulsions for one year; then vomiting, headache, weakness, staggering gait; next day diplopia, vertigo; paræsthesia; hunger.	Left facial palsy; paresis of left arm and leg; stiffness of arms and legs, with paræsthesia; slight ptosis of right eye.	Diagnosis and operation impossible.
8	Fleischmann, in Steffan, l. c. p. 625.	F. 5	Tubercular tumor on under surface of left frontal lobe; another at summit of convexity of right hemisphere; tubercular meningitis.	Headache; vomiting; attacks of screaming.	Left third paretic; later, right third paretic.	Diagnosis and operation impossible.
9	Escribano, in Bernhardt, l. c. p. 108.	M. 18	Two tumors, size of chestnuts, in left frontal lobe.	Headache; vomiting; epilepsy.	None.	Diagnosis and operation impossible.
10	Morgan, in Bernhardt, l. c. p. 97.	F. 7	Large echinococcus cyst in right anterior and middle lobes, destroying basal ganglia.	Intelligence weakened; pupils dilated, later blindness; convergent strabismus of left eye; numbness and weakness of legs; later, incoördination and contractures.	None.	Healthy-looking child; other cysts elsewhere. Diagnosis and operation impossible.
11	Reimer, in Steffan, l. c. p. 631.	M. 5	Tubercular tumor in right centrum ovale at junction of frontal and middle lobes surrounded by a zone of softening; tubercular meningitis.	Frontal headache; vomiting; attacks of screaming; slow pulse, at times irregular; delirium; convulsions; sopor.	None.	Rachitis; scrofula. Diagnosis and operation impossible.
12	Rothmund, in Bernhardt, l. c. p. 99.	F. 13	Sarcoma, size of hen's egg, in middle lobe of right hemisphere.	Periodical headache, with vomiting; optic neuritis; sudden death during attack of headache.	None.	Diagnosis and operation impossible.
13	Visconti, in Bernhardt, l. c. p. 98.	M. 18	Large echinococcus cyst in right hemisphere.	Periodical headaches; right tinnitus aurium; occasional loss of consciousness; staggering gait.	Double vision; trigeminal nerve very sensitive; retraction of head and neck; tetanic spasms of neck before death.	Diagnosis and operation impossible.
14	Arnott, in Bernhardt, l. c. p. 97.	M. 4½	Four tubercles in right hemisphere, each size of hen's egg.	Convulsions; death in coma.	Paralysis of right arm.	Diagnosis and operation impossible.
15	Merkel, in Steffan, l. c. p. 632.	M. 5	Four cysts in left hemisphere in its parietal lobe	Headache; general convulsions.	Gradual paresis of right arm, with deficient growth.	Left parietal bone thin and bulging. Diagnosis and operation impossible.

TABLE II.—*Continued.*

No.	Author; reference	Sex, age.	Variety and position of tumor.	General symptoms.	Local symptoms.	Remarks.
16	Steffan, l. c. p. 626.	M. 2	Cancerous mass on base and in right temporal lobe.	No cerebral symptoms.	Cancer of right eye was removed.	Diagnosis and operation impossible.
17	Hutchinson, in Bernhardt, l. c. p. 103.	F. 13	Hard tumor, size of nut, in the middle of the left frontal lobe, with surrounding softening.	Symptoms followed an injury of the head.	Right-sided spasms; gradual contracture of right arm; anæsthesia of back of right hand; paresis of right leg.	Diagnosis possible; operation possible, but expectation of cortical tumor being disappointed, deep incision to find tumor necessary.
18	Glynn, in Bernhardt, l. c. p. 123.	M. 13	Tumor, size of orange, in white matter of both right central convolutions.	Headache; optic neuritis; blindness.	Left-sided spasms; left hemiplegia.	Diagnosis only probable, unless location of spasms and progress of paralysis were noticed. Operation possible.
19	Assagioli, in Roland, l'Epilepsie Jacksonienne, case 63.	F. 10	Tubercular mass of irregular shape in cortex of paracentral lobule and quadrate lobule of left hemisphere.	None noted.	Spasm beginning in right leg and extending to arm, back, neck, and face, in order named; spasms at times in right leg only.	Diagnosis and operation possible.
20	Osler, American Journ. Med. Sci., 1885, i 31.	F. 15	Glioma in upper third of anterior central convolution under the cortex on right side	Injury to head when an infant: symptoms intermitted for some years.	Spasms beginning in left hand or in left foot, extending to face; left leg paretic and contracted.	Diagnosis and operation possible.
21	Connor, cited by Starr, Amer. Journ. Med. Sci., case lxv., 1884.	M. 17	Cystic glioma in right centrum semiovale under upper half of anterior central convolution, and invading frontal convolution.	Headache; optic neuritis; convulsions; gradual mental failure; delirium; loss of sphincter control; duration two years.	Spasms and paresis of left arm, increasing to paralysis in it four months before death.	Diagnosis possible four months before death. Operation possible then, but prognosis bad.
22	Janeway, cited by Starr, l. c., case lxvi.	M. 13	Glioma, size of orange, firm, lobular in upper two-thirds of right convolutions, extending into adjacent gyri.	Fall on head, followed in two weeks by headache, then by vomiting, in fourth month; death in fifth month.	Two weeks after fall paresis of left arm and leg; then spasms in left shoulder, arm, and hand; in five months left arm and leg weak, stiff; pain in left leg; left ear deaf; smell lost in right nostril.	Diagnosis possible at four months. Operation possible then with good results.
23	Reimer, in Steffan, l. c. p. 624.	M. 12	Six tubercular tumors in anterior central convolution of each hemisphere.	Headache; weakness; nausea; vomiting; blindness; duration two years.	Spasms in left leg and arm; spasms in right side; paresis of left leg and right face, and slight anæsthesia in both.	Chronic pneumonia; tubercular glands. Diagnosis of multiple tumor possible; operation impossible.
24	Seeligmüller, Jahrbk. f. kindheilk., xiii. p. 322.	F. 4	Tubercle in right anterior central convolution in middle third, size of cherry.	Tubercular glands in neck.	Spasms of left arm daily or oftener, followed by paresis of left arm for two months before death; internal strabismus of left eye.	Diagnosis and operation possible.
25	Duchek, in Bernhardt, l. c. p. 65.	M. 8	Tubercle in convexity of left hemisphere extending inward toward the optic thalamus.	General tuberculosis.	Spasms of right arm, extending to the face; later right leg involved in the spasm; finally, right hemiplegia.	Diagnosis and operation possible; operation unadvisable in view of general tuberculosis.
26	Gliky, in Bernhardt, l. c. p 66.	M. 15	Glioma in both right central convolutions with invasion of adjacent areas.	Headache in right temple; vomiting.	Spasms in left arm, with weakness, and finally, atrophy of the arm, without anæsthesia; left hemiparesis with twitchings in extremities.	Diagnosis and operation possible, early.
27	Morelli, in Bernhardt, l. c. p. 67.	F. 18	Tubercle in middle third of left posterior central convolution, extending forward and inward toward lenticular nucleus.	No tuberculosis elsewhere.	Spasms of right arm, followed by choreic movements in right arm; the spasm occasionally extended to the right leg; pain in right arm.	Diagnosis possible; operation possible and advisable.
28	Rosenthal in Bernhardt, l. c. p. 72.	M. 17	Tubercle in middle third of left anterior central convolution, involving second frontal convolution slightly.	Headache; vomiting; vertigo; tuberculosis not mentioned.	Spasm of right hand, extending to right face, followed by paresis in both; pain in right hand.	Diagnosis and operation possible.
29	Henoch, in Bernhardt, l. c. p. 74.	M. 2	Tubercle in middle third of left anterior central convolution; localized tubercular meningitis over left frontal lobe.	Somnolence; nystagmus of left eye; tuberculosis not mentioned.	Tremor of right arm; twitching of right corner of mouth; later, tremor of head and right leg, with spasms of right side of trunk and abdomen; paresis of right arm.	Diagnosis and operation possible after onset of paresis in arm.

TABLE II.—*Concluded.*

No.	Author; reference.	Sex, age.	Variety and position of tumor.	General symptoms.	Local symptoms.	Remarks.
30	Barling, Trans London Path. Soc., p. 42, 1887.	M. 12	Tubercular tumor at upper part of left central hemisphere at junction of anterior and middle lobes; on surface large as walnut, easily separable from brain tissue; similar smaller tumor on base of same hemisphere.	Convulsions; symptoms of albuminuria; mental dulness.	Spasms of right side without loss af consciousness continuing for five days, followed by partial paralysis of right arm with some jerky movement The paralysis increased and extended to right face and leg; death after five weeks.	Diagnosis and operation possible, but second tumor would not have been detected.
31	Duchek, in Bernhardt, l. c. p. 68.	M. 18	Tubercle of "summit" of left hemisphere in the central area, extending downward toward the optic thalamus; softening around it.	Convulsions.	Spasms in right arm and leg, often beginning in the leg; later, right hemiplegia.	Diagnosis and operation possible.
(*a*)	Sodermark, Jahrb. f. kinderhk., xxiii 462.	M. 3	Hard, gray tumor, size of pear, in left lateral ventricle; congestion of membranes.	Headache; vomiting.	Flexor contraction of right arm, and spasms of right arm and face occurring daily in attacks during which he cried and was alarmed, and in which eyes were turned to right.	Diagnosis and operation impossible; probable diagnosis of cortical tumor in motor area would have been wrong.
(*b*)	Rolland, l. c. p. 44.	F. 14	Sarcoma in left ventricle and in optic thalamus, undermining frontal convolutions.	Headache; blindness; growth of head; general weakness.	Attacks of right-sided spasms, beginning in right hand and extending to entire body.	Diagnosis and operation impossible; probable diagnosis of cortical tumor wrong.
32	Buzzard, Lect on Dis. of Nerv. Syst., pp. 429 and 437.	F. 14	Small red tumor, size of walnut in white substance of left hemisphere above middle of lateral ventricle.	.....	Epilepsy with loss of consciousness, aura beginning in left wrist, which was transferred to right wrist by circular blister.	Diagnosis and operation impossible; probable diagnosis from aura of tumor in motor area wrong. In last three, operation might have been undertaken, but must have failed.
33	Ciccimarra, in Bernhardt, l. c. p. 105.	M. 9	Echinococcus cyst, size of fist, in left parietal region, reaching lateral ventricle.	Headache; vomiting; convulsions; blindness; duration ten weeks.	Facial spasm on left side; hallucinations of light with blindness (Visual field not tested.)	Diagnosis and operation impossible.
34	Smith, in Bernhardt, l. c. p. 106.	M. 5½	Fibro-sarcoma, with cyst size of orange, in right parietal and occipital lobes.	Headache; weakness and tremor of all limbs; rigidity of back and legs; paralysis of sphincter; convulsions; optic neuritis; vomiting; nystagmus and internal squint.	(Visual field not tested.)	Diagnosis and operation impossible.
35	Henoch, in Bernhardt, l. c. p. 74.	M. 1	Tubercle, size of pigeon's egg, in left occipital cortex; tubercular meningitis.	Stupor; convulsions; apathy; anæsthesia.	(Vision and field not tested.)	Diagnosis and operation impossible.
36	Fleischmann, in Steffan, l. c. p. 625.	F. 8	Tubercle, size of hen's egg, in left occipital lobe; second tubercle in right hemisphere of cerebellum.	Headache for a long time; general convulsions; blindness, with optic neuritis.	Right eye first became blind. (Visual field not tested.)	Diagnosis and operation possible, if hemianopsia had been found; second tumor would have been undetected.
37	Koster, in Bernhardt, l. c. p. 108.	F. 5	Gliosarcoma, size of lemon, in left occipital lobe, nearly reaching thalamus.	Headache; delirium; optic neuritis; hunger; restlessness.	Difficulty in finding words in speech. (Sensory aphasia. Visual field not tested.)	Diagnosis and operation possible if hemianopsia had been found.
38	Huguenin, in Seguin on Hemianopsia, Journ. Nerv. and Men. Dis., p. 23, 1886.	F. 8.	Tubercular tumor near apex of right occipital lobe on mesal aspect in cuneus; second tumor at apex left frontal lobe.	Headache; optic neuritis; vomiting; insomnia; general convulsions; dementia.	Left homonymous hemianopsia; appeared late.	Diagnosis and operation possible after hemianopsia appeared; second tumor would have been undetected.
39	Bagg, cited by Starr, l. c., case xlii.	M. 13	Carcinoma in left temporo-occipital lobe.	Headache; blindness; exophthalmos; muscular pains.	Visual field not tested.	Diagnosis and operation impossible.
40	Mills, Journal Mental and Nervous Diseases, p. 716, 1887.	F. 12	Glioma of right temporal lobe 3 x 1½ x 1½ in, with extensive hemorrhage in cavity.	Fall, followed by headache in right temporo occipital region, where tenderness was present; slight blindness; stupidity; optic neuritis.	Paralysis of arm and paresis of leg on left side came on suddenly in seventh month; speech thick and indistinct.	Diagnosis and operation impossible, though carefully considered.

bly general convulsions. These present themselves in rapid succession because the situation of the tumor beneath the tentorium cerebelli is such as to obstruct the venous flow from the venæ Galeni, and the free interchange of fluid between and through the ventricles, and to produce both general hydrocephalus and a stretching of the dura mater which are supposed to cause many of the general symptoms of brain tumor. It may be remarked that while headache is almost invariably present in cerebellar tumor, and is often referred to the back of the head, it may be felt at any part of the head, and is as frequently frontal or temporal, as it is occipital. In many of the tumors here collected, the headache was entirely frontal. The pain does not indicate, therefore, the seat of the tumor. Tenderness to percussion over the occiput is, however, a valuable sign of cerebellar disease.

But, in addition to the general symptoms of tumor, there are local symptoms of great value. These are vertigo and cerebellar ataxia, or the staggering gait. The patient feels himself falling in a certain direction, staggers in walking, and often staggers toward one side with remarkable constancy. Time does not permit of a discussion of the origin of these local symptoms, but they are of great value. Their occurrence indicates that the middle lobe of the cerebellum is either the seat of the tumor, or is encroached upon by a tumor in the hemispheres. If they occur quite early in relation to the general symptoms, it is the middle lobe in which the tumor began. If they occur late, after many months of suffering, the tumor has started in a hemisphere, given rise to general symptoms, and has at last reached the middle lobe and produced the local symptoms. The question at once arises, In which hemisphere has it begun? And here we are often in the dark. Patients are said to stagger, in walking, away from the side on which the tumor lies. Nothnagel and Bramwell affirm this, and I have seen four cases in adults in which this has been true as shown by autopsy. But if there is no tendency toward one side in walking, there may be a tendency to fall forward or backward. As yet, no assertion is possible as to the significance of this symptom, as it is impossible during life to determine whether it is due to irritation or destruction of tissue.

When these symptoms fail it is sometimes possible to determine which hemisphere is invaded by the tumor, by observing on which side cranial nerve symptoms, such as strabismus, facial anæsthesia or paresis, deafness, or retraction of the head, appear. They usually come first on the side of the tumor, as this, by its presence, crowds the cerebellum down upon the base of the brain and presses on the nerves. Paralysis of one fourth nerve, though difficult to detect, is a valuable symptom, as it always occurs on the side of the tumor.

By compressing one side of the pons or medulla a tumor may cause paresis or numbness, or increased reflexes in the opposite arm and leg, and these symptoms may aid the diagnosis. Many of these local symptoms were present in a case under my care and subsequently seen by Dr. Lewis Smith, and they enabled a correct diagnosis of the seat of the tumor to be made.[1]

The diagnosis being made, the question of operation arises: Can tumors of the cerebellum be removed? The cerebellum presents but one of its three surfaces to the skull, and there is, as yet, no means of determining whether a tumor is near that surface or not. Any operation must, therefore, be primarily exploratory.

In case a tumor is seen upon the exposed surface, it may be removed. But great care should be observed in the manipulations about the cerebellar hemispheres in order that the medulla may not be compressed, or the pneumogastric nerves torn or stretched in the process. Three cases of cerebellar tumor in young persons have been removed, and in all three death occurred within forty-eight hours, apparently from shock, although no special reason for shock existed. These cases were as follows:

CASE I. *Tubercular tumor of cerebellum* (V. Horsley, *British Medical Journal*, April 23, 1887, i. p. 865).—Male, aged eighteen, had suffered from progressive symptoms; headache, vomiting, optic neuritis, increasing weakness of all limbs, especially the left arm and leg, and epileptoid attacks with turning of head and eyes to the right; mental state good. He had been in bed a year. Diagnosis, by Dr. Bastian, of tumor involving the right lobe of the cerebellum. A tubercular tumor seven drachms in weight was removed from the right lobe, but the patient died nineteen hours after operation.

CASE II. *Tubercle of cerebellum* (Bennett May, *Lancet*, April 16, 1887, i. p. 768).—Male, aged seven, suffered in April, 1886, from headache, chiefly frontal, vomiting; then gradual failure of sight occurred, and in July he was nearly blind. In July paralysis of the right sixth nerve was found and eyes were turned to the left. Optic neuritis was found in both eyes. Gait was staggering, chiefly backward and to the left. Mind was clear. In August, headache and vomiting were severe, he could not stand, and head was retracted. In October, he was blind; nystagmus was noticed; there was emaciation; and knee-jerk was lost on right side.

He was operated on by Dr. May: the cerebellum was exposed on the right side of the median line, and appeared healthy but bulged, and was felt to be hard at one spot. After incision a tumor was felt one inch below the surface. This was dug out with the handle of a spoon. It was larger than a pigeon's egg, hard on the surface, caseating at its centre. Hemorrhage was slight; but the child died of shock a few hours afterward.

CASE III. *Glioma of cerebellum; operation* (C. W. Suckling, *Lancet*, October 1, 1887, ii. p. 656).—Female, aged twelve, complained of headache and vomiting for one and a half years, then for nine months of weakness in the right arm and leg, and then for three months of severe headache in forehead above the right eye. For last month had noticed an inability to move the eyes outward to either side and l. > r. pupil, and gradual onset of double vision and blindness. From the first there

[1] Archives of Pædiatrics, vol. v. p. 278.

had been tremor in right arm on exertion. Vertigo had been present for some time, and staggering with a tendency to fall forward.

On admission to hospital, March 28, 1887, weakness of right arm and leg, and of left face, deviation of tongue to right; optic neuritis, nystagmus on any motion of eyes, loss of conjugate motion of eyes to right, and great impairment of the left. Diminution of knee-jerk, greater on right side, great staggering to left side; headache, vomiting, and vertigo were found.

The occipital bone was trephined over the left side, and the cerebellum exposed. The brain bulged out, and its tissue appeared darker and softer than normal. A part of the cerebellar substance was cut away, and the wound was dressed. The patient collapsed and died in forty-eight hours. The autopsy showed that the glioma had occupied the entire left lobe of the cerebellum and had invaded the middle lobe also.

In case no tumor is seen on the exposed surface of the cerebellum, what can be done? It is impossible to obtain access to the upper and anterior surfaces of the cerebellum from the posterior surface by pressing the organ to one side, for it is situated in a small cavity, and pressure downward causes dangerous compression of the vital nuclei of the medulla, while lifting it upward endangers the pneumogastric nerves. The only method of proceeding is exploratory incision. This was practised by May and revealed the tumor an inch beneath the cortex. He found the tumor encapsulated, and he removed it with ease, but the boy died in collapse.

The question will arise, How deeply can the cerebellum be incised? No facts are at hand to enable us to answer. It must be remembered, however, that in physiological experiments much of the cerebellar hemispheres may be removed without danger so long as the middle lobe and dentate nuclei of the hemispheres be not encroached upon. It remains to be seen whether the removal of a tumor of the middle lobe of the cerebellum, which has produced staggering gait, can be followed by recovery; but judging from physiological experiments it seems improbable.

The conclusion, therefore, regarding tumors of the cerebellum is that in about one-third of the cases the surgeon can reach the tumor; that the operation is essentially exploratory; and that it is much more dangerous to life than operations upon the cerebrum; and that no recoveries have as yet been recorded.

Multiple tumors form the next class in the table, and these must be at once dismissed as outside the field of operation at the present time. It may be remarked in passing that where numerous local symptoms are present in a case, which cannot be explained by a single lesion, the diagnosis of multiple tumor is justifiable.

The remaining classes are tumors of the cortex and tumors of the centrum ovale, fifty-six in number. Both these classes of tumors can be reached by the surgeon. There are no especial indications for their detection or removal in children as distinguished from adults.

The entire subject of diagnosis and removal of cortical and subcortical tumors has been so fully discussed recently, by Seguin and Weir, and by Keen in the *American Journal of the Medical Sciences*, that nothing remains to be said upon this point. It may be of interest, however, to consider these cases critically and to ask three questions regarding each, viz.: Could the diagnosis of the location have been made? If so, could the tumor have been reached? If so, was it of a nature to allow of removal?

In order to determine these points I have abstracted and tabulated forty of these cases, the remainder being of a character, both clinically and pathologically, to baffle both diagnosis and surgical treatment. Of these forty, there were thirteen in which a diagnosis of the exact position of the tumor could have been made during life, and an operation properly conducted would have resulted in the removal of the tumor. All of these cases[1] were tumors of the central convolutions, giving rise to local spasms followed by paresis. The starting-point of the spasm, its order of extension, and its limitation; the character of the paresis, its situation of greatest intensity or longest duration, when temporary, and its order of extension, were the symptoms in each of these cases which should have enabled the physician to determine the seat of the tumor. In none of them could the surgeon have been misled by following these signs of localization, and in all but two the operation would have been successful, as the tumors could have been reached and removed. In two, however, the tumor was gliomatous, and infiltrated the brain tissue too extensively to admit of complete excision.

In six cases among the forty a more careful examination of the case would have enabled a localization to be reached. Then in two cases of the central area the character of the spasms, and the order of extent of the paralysis were not recorded. And in three cases of the occipital region no test of the visual field was made, and hence hemianopsia, a very important localizing symptom, probably present, was not noticed. In five of these six cases[2] had the diagnosis been made, an operation might have been successful. In the other case[3] it would have failed, as there were several tumors.

In twenty-one of the forty cases the diagnosis of the seat of the disease was absolutely impossible, and hence no question of surgical interference could have arisen. It is true that in view of the post-mortem findings many of these tumors might have been removed successfully by operation had a diagnosis been reached.

[1] Cases 17, 19. 20, 21, 22, 24, 25, 26, 27, 28, 29, 30, and 31.
[2] Cases 2, 18, 36, 37, and 38.
[3] Case 23.

Two cases of tumors within the brain have been added to the collection,[1] one in the optic thalamus, the other in one lateral ventricle, in order to demonstrate how both diagnosis and operation might fail. In both of these cases the symptoms might easily have led to a diagnosis of cortical tumors in the motor area, but had an operation been undertaken, no tumor would have been found. Such cases should serve as a warning. They teach that under the most careful examination diagnosis is never absolutely accurate, and that many operations must necessarily be exploratory. This latter fact, however, is familiar to surgeons, and need not prevent the progress of cerebral surgery.

To sum up the results of this analysis of forty cases, we may say that in nineteen an operation was indicated, and in sixteen it would have been successful.

In the collection of cases of subcortical tumor there remain sixteen not tabulated, because in all of these the diagnosis during life would have been impossible, and an operation would not have been feasible. These then must be added to the unfavorable cases. The result then is that sixteen cases out of fifty-six could have been successfully treated by excision.

Out of 300 cases then of brain tumor in children, 19 cases only warranted an attempt at surgical interference, and of these only 16 would have been successful.

When the character of these 16 tumors is studied, it is found that 3 were gliomata, 1 was an echinococcus cyst, and 10 were tubercular tumors, the others being undetermined. If it is thought unjustifiable to operate on tubercular tumors, there remain but 6 out of 300 tumors fit for operation.

It may be remembered that in a review of 100 tumors in the museum of Guy's Hospital, Dr. Hale White found 10 which might have been removed safely. His percentage, ten per cent., is much larger than my percentage—five per cent. including tubercular, and two per cent. excluding such tumors.

This conclusion appears to be very unfavorable to surgical interference in brain tumors in children. It is to be remembered, however, that in many cases the patients were only observed in a late stage of the tumor, when it had grown to such a size that early local symptoms were obscured, as they are likely to be, by later symptoms. And it is also to be remembered that at present the observation of nervous symptoms is more careful and accurate than in former years.

It is not too much to hope that the records of the next twenty years may show a much greater per cent. of tumors diagnosticated and successfully treated. But at the present day when the tendency is, perhaps, setting toward cerebral surgery, a conservative view, and a wholesome caution may be fostered by a study of the past, such as the present paper has given.

[1] Cases *a* and *b*.

A NOTE ON THE USE OF THE BIDET IN SURGERY.

BY J. WILLIAM WHITE, M.D.,

DEMONSTRATOR OF SURGERY IN THE UNIVERSITY OF PENNSYLVANIA, ASSISTANT SURGEON TO THE UNIVERSITY HOSPITAL.

I DESIRE to call the attention of the profession to a method of treatment which, although not altogether new, is yet not appreciated as, in my judgment, it should be. I refer to a moderately forcible stream of water of varying temperature in the treatment of a number of affections of the rectum, anus, and genito-urinary apparatus. The atonic and astringent effect of such a stream of water upon any living tissue is, of course, a well-understood[1] fact, and has been employed in the arrest of hemorrhage, in the treatment of inflammation, and in various other conditions. But it has only been in exceptional cases, and usually by the aid of more or less troublesome apparatus that it has been used in the class of cases to which I now refer.

The bidet, as I have now for a few years prescribed it, should be of the variety which can be attached to the water-closet seat habitually used by the patient. It should have a nozzle capable of throwing a stream of about the calibre of an ordinary lead pencil or a little less. The head of water should be sufficient to make it impinge upon the parts exposed to it with enough force to excite there a little sensation of smarting and tingling. That degree of force will, for example, be sufficient to enable the patient to take an enema, or, if a female, to take a vaginal injection. The bidet pipe should be movable by means of a handle, so that the stream can be directed against any portion of the external genitals, the perineum, the anus, or the surrounding parts. It should also have connection with the hot and cold water supply of the house, so that the water may be used of any temperature which the physician may prescribe, or which the sensations of the patient may make desirable. Stopcocks should regulate the size and force of the stream, and should be so placed as to be easily reached by the hand of the individual sitting upon the water-closet seat. Such an apparatus can be put in place by an experienced plumber, in any ordinary water-closet, at an expense of from fifteen to twenty dollars; and, in this city at least, the usual head of water obtainable even in third-story rooms is quite sufficient for all therapeutic purposes.

The cases in which it may be desirable to use this

[1] Agnew (Surgery, vol. i. p. 445): "There is something peculiar in the action of a fine stream of water; it produces a much more energetic contraction of muscular fibre than that caused by bathing orsponging."

method of treatment may be divided into two classes: first, those affecting the lower end of the bowel and its outlet; second, those involving the genito-urinary system. Among the first the most important are hemorrhoids, internal and external, prolapsus ani, and slight cases of prolapsus recti; pruritus ani and eczema of the margin of the anus should also be included in this group of cases in which it has now for some time been my habit to prescribe the systematic employment, twice daily, of the bidet, once immediately after the daily stool, and for the second time, by preference, just before going to bed. As a rule, in all but the mid-winter months, the ordinary temperature of Schuylkill water is that to be preferred, although I am largely governed by the feelings of the patient in this respect. An enema should be taken at each of these times, the lower portion of the rectum being thus thoroughly washed out at least twice daily, after which the stream of water is allowed to play upon the affected region for a period of from five to fifteen minutes. The ordinary and useful effect of cool sponging or washing immediately after stool in cases of hemorrhoids is by this means enormously increased; internal hemorrhoids will, under this treatment, in many cases almost entirely disappear, unless they are exceedingly large and have been frequently inflamed or strangulated and badly neglected; external hemorrhoids, even when fleshy, will shrivel and become scarcely noticeable.

I could detail a number of cases of this character taken from my practice of the last two years. In some instances in which I had been habitually called in, at intervals of a few months, in the cases of old people the result has been practically their disappearance from my list of patients; and they speak in the warmest manner of the great comfort which they have derived from this simple method of treatment.

Perhaps nothing is more distressing among minor afflictions than the trouble described as pruritus ani, and variously attributed to liver disease, constipation, gastric troubles, latent gout, uterine disease, parasites, neuroses, and a number of other causes, varying from the eating of shell-fish, or excessive smoking, to alleged hereditary predisposition. There are very few practitioners of any experience who have not discovered how difficult it is, in any particular case of pruritus, to assign distinctly the annoying symptoms to any one of these causes. Often the whole list may be carefully gone through and eliminated, or the proper remedies may be applied successively, as different theories are adopted, without the slightest benefit resulting. Ointments, lotions, *ordinary* cool bathing will be tried in great variety, but without avail; and such patients will often go from one physician to another, or will fall into the hands of quacks while seeking relief. My list of cases of this character which I have now treated by means of the "bidet" comprises eight, one of which it may be worth while to mention in a little more detail.

Mr. —, aged thirty-five, a lawyer by profession, of somewhat sedentary habits, but in good general health, applied to me, in January, 1887, on account of a long-continued pruritus, which, he said, was simply making life miserable to him; he was a man of great intelligence, who had secured the best medical advice in this and other cities, and who gave a graphic description of his sufferings. Whenever, after sitting for a time at his desk, the buttocks and perineum became warm, itching would begin, and would presently become intolerable, so that he would be absolutely obliged to rise, and, if he was not alone, to make some excuse to leave the room, in order to obtain ease, temporarily, by scratching. At night, after he became warm in bed, his trouble—as is usually the case with such patients—became much worse, so that often a large part of the night was rendered sleepless, and the sleep which he did procure was broken and disturbed. He frequently awakened with a start, finding himself digging at the parts with his nails. He was losing flesh rapidly, was becoming unable to attend to the ordinary duties of his profession, was annoyed and mortified, even when in court trying cases, by the almost irresistible impulse which he felt to apply friction to the irritated region, and naturally was intensely depressed and despondent.

He brought me copies of the prescriptions which had from time to time been given him, and which covered almost the entire ground of the above mentioned list of possible causes. I had—fortunately for him and for myself—just been successful in a case of much less severity, in procuring relief and apparent cure by means of the bidet; I promptly prescribed it for him, instructing him, as it was January, to use the water at a temperature a little short of tepid, and prescribed, in addition, only an ordinary oxide of zinc ointment, for the relief of a little eczematous irritation produced by his scratching. His improvement was immediate and marked, and at the end of two weeks he said that he had merely a trace of his former trouble, which soon after entirely disappeared, and he has ever since remained free, although he has been compelled to take long trips away from home, and thus obliged to intermit his treatment.

Some of my other cases are of equally striking character. They have nearly all resulted in cure; requiring to attain that end simply different lengths of time of the application of the douche, with variations in the temperature of the water, and occasionally the use of some emollient salve. I have been particularly struck by the fact that these cases include among their supposed causes widely distinct conditions, and the uniformity with which they have yielded to this simple treatment has led me to regard with suspicion the orthodox etiology of the disease. In procidentia ani, and in slight cases of prolapsus recti, I have had

very satisfactory though, of course, less striking results. In a few instances the trouble almost entirely disappeared, and in all of them it was distinctly relieved. These cases require for their successful treatment a much longer application of the douche, and the water should, in my judgment, be at one or the other extremes of temperature, either quite cool, or as hot as can comfortably be borne.

I am quite aware that the use of cold water in these affections is not in the least a novel plan of treatment; but the method under consideration combines the effects of temperature with a sufficient force of the stream, and admits of the prolonged application of the remedy without effort on the part of the patient, who is in the most suitable position for this treatment, practical points which induced me to make this mention of my results in rectal and anal cases.

Agnew says of pruritus, that among the local remedies frequent ablutions with cold water should be mentioned; and of prolapsus ani et recti, that "in all cases where remedies have proved unavailing, or where patients have declined an operation, much good may be done by douching the parts with cold water and applying an oiled compress;" and Allingham says of the same class of cases, that "the frequent and bountiful application of cold water is to be most strongly recommended;" but few authors, so far as I know, have especially alluded to the method of application by means of a bidet.

My second class of cases includes, chiefly, certain prostatic troubles, varicocele, atonic impotence in the male, and pruritus of the vulva or vaginitis in the female. In cases of varicocele, although I have not succeeded in effecting a cure in any instance by this method, I have certainly seen advancing enlargements of the spermatic veins become stationary; long, relaxed, and pendulous scrotums become firm and much smaller; and the mental condition of the patient—which is so important an element in many of these cases—share in the improvement. In chronic prostatitis, a most intractable and distressing ailment in many instances, it has come to be a part of my routine treatment to order the use of cold perineal douches by means of the bidet, associated with frequent cool enemata given in the same manner; and I believe to-day that if I had to discard all therapeutic measures but one in these cases, I would retain this one. In a certain number of cases of impotence associated with general muscular weakness, loss of tone, lack of general strength and vitality, accompanied by imperfect or rapidly subsiding erections, I have found that the cold douche applied with some force and for considerable lengths of time to the perineum and testicles has been productive of marked benefit.

In two cases of pruritus vulvæ my results have been good, though less striking than in the similar disease affecting the region of the anus. In vaginitis, where the woman has sufficient intelligence to learn how to take an injection by means of the bidet, it offers an admirable method of cleansing the vagina, of carrying away thoroughly all accumulated secretions, of reducing heat and swelling, and at the same time of avoiding the frequent introduction into the inflamed canal of a foreign body in the shape of the nozzle of a syringe. My opportunities for observation in this class of cases have been limited, owing to the disinclination of these patients to procure the bidet, and owing to their irregular habits of life and their frequent changes of residence; but I have seen enough of its good results to make me feel confident that it is a valuable addition to our therapeutic agencies.

After all, in every one of the cases which I have mentioned, its use is simply the application of the most elementary and common-sense principles to everyday practice, but I am satisfied that this particular method of applying these principles has not received the attention which it merits.

A SUCCESSFUL CASE OF VAGINAL HYSTERECTOMY.

BY RANDOLPH WINSLOW, M.A., M.D.,
PROFESSOR OF SURGERY IN THE WOMAN'S MEDICAL COLLEGE OF BALTIMORE; LECTURER ON CLINICAL SURGERY IN THE UNIVERSITY OF MARYLAND.

AMONGST the moot points which are occupying the attention of the medical profession at this time, none, perhaps, is of more practical importance and interest than the subject of the treatment of cancer of the uterus. Everyone is familiar with this horrible disease, with its fetid discharge, frequent hemorrhages, disturbances of the functions of the bladder and rectum, and pain. The course of such a malady is too well known. The patient becomes disgusting to herself and to her friends alike, and the end is looked forward to as a blessed relief.

All surgeons agree that something ought to be done to mitigate the sufferings of those who are stricken with this fell disorder, and, if possible to effect a radical cure; but it is a disputed question whether a partial operation, one which aims to remove a portion of the uterus only, should be performed, or the complete extirpation of the organ. In favor of the partial operation is the very much smaller mortality of the procedure itself; against it is the fact that a cure is seldom effected, the fatal termination being usually only averted for a time. Again, a partial operation would be of no avail if the disease had either originated within the cavity of the uterus or had extended upward from the cervix. In favor of complete hysterectomy is the fact that the whole disease is much more likely to

be eradicated, and a permanent cure to be effected; whilst opposed to this advantage is a higher rate of mortality.

Such then is the question as it confronts us at this time. The weight of authority in Germany is in favor of complete extirpation, whilst in this country the conservative operation has, until recently, received universal professional sanction. It does seem to me, however, unreasonable that an exception should be made in the case of the uterus, to the accepted law, that the whole of an organ should be removed for malignant disease when such can be accomplished with a reasonable rate of mortality. Whilst opportunity does not serve me to go into an extensive consideration of the mortality of vaginal hysterectomy, it may be stated that the death-rate is diminishing each year, and has fallen from 29 or 30 per cent. to about 10 per cent., and will, probably, still further decrease as surgeons acquire a greater familiarity with the technique of the operation. Dr. August Martin, of Berlin, collected, in 1887, 311 cases with a fatality of 47 or 15.1 per cent., and this rate has still further decreased to between 10 and 11 per cent. Dr. Martin likewise states that 70 per cent. of permanent cures have been obtained by vaginal hysterectomy.

It is a duty which one owes to the profession to place upon record his cases, whether successful or otherwise, and in obedience to that mandate I publish the following case of total vaginal hysterectomy:

Mrs. S., widow, forty-two years of age, two children, now grown, was a fine-looking and healthy woman previous to the past eight months. For some months she has been having a foul discharge from the vagina, with metrorrhagia, but not much pain. She came under my observation in July, 1888, at which time she was anæmic and weak, with no appetite, a feeble, quick and thready pulse, constant cough, and unable to sleep. A vaginal examination revealed a large proliferating epithelioma of the cervix uteri, which nearly filled the vagina, but did not involve it. On September 6, 1888, the cervix was removed flush with the vaginal junction, with the curette and scissors, at which point the tissues were hard and apparently healthy; and the face of the stump was thoroughly rubbed with nitrate of silver. There was free hemorrhage until firm tissue was reached, when it ceased. The vagina was irrigated with hot water, which arrested all oozing. A pad of styptic cotton was placed against the stump, and the vagina partially filled with iodoform gauze. The anæsthesia, ether, was very well maintained, and her feeble pulse improved during the operation. The patient did exceedingly well, gained appetite and flesh, improved enormously in appearance, and in a few weeks was down-stairs and out.

After six or seven weeks, backache and shooting pains returned, necessitating the use of anodynes, and there was a tendency to bleeding; and upon examination the cervical stump was seen to be proliferating again. Total extirpation of the uterus was suggested as the only remedy likely to be of any avail, and the gravity of the operation was clearly explained. Without any solicitation on my part and against the urgent entreaties of her friends, the patient decided to submit to hysterectomy, remarking that she would rather die under the operation than live six months suffering as she did. At this juncture I availed myself of the opinion of my friend, Prof. Ashby, who agreed that the case was one suitable for extirpation. During the two weeks in which the patient was considering the advisability of the operation, the disease made steady progress, pain became constant, and her strength began to fail. November 13, 1888, was the day appointed for the operation, at which I was assisted by Prof. Jay, and Drs. C. Winslow, J. R. Winslow, and F. M. Latham. Ether narcosis. The bowels had been moved, and the bladder catheterized previous to operation. After cutting the vulvar hair, and washing and disinfecting the external genitals, the vagina was thoroughly irrigated with bichloride solution 1 : 2000

Operation.—Incised posterior vaginal wall with long scissors, and after cutting through the mucous membrane I gradually dissected up the tissues with the finger until the peritoneum was reached at a great distance from the vagina. The cervix was very friable and the vulsellum forceps kept tearing out, causing considerable hemorrhage, which obscured the field of operation. The anterior wall was now incised and after a long dissection the peritoneum was reached and opened. The lateral vaginal walls were divided around the cervix, and the fingers passed around the left broad ligament, and a stout double ligature carried from the anterior to the posterior opening, and firmly tied. As an additional security the ligament was clamped with two catch forceps, which were left *in situ*. The uterus was now completely severed from all its attachments on the left side, and brought down into the vulvar opening. The left ovary came into view and was removed; the right ovary was not seen. The right broad ligament was ligated and clamped in the same way as the left, and the uterus removed. Some bleeding points were clamped, and six pairs of forceps were left hanging out of the vagina. The vagina and pelvis were irrigated with hot weak bichloride solution, and then with plain hot water, until all oozing ceased and the water returned clear. It was impossible to prevent blood from getting into the pelvic cavity. The intestines came into sight, but did not interfere with the operation.

The operation was much more difficult than I had expected, owing to the size of the uterus, and the elongation of the supra-vaginal portion of the cervix, and the hemorrhage from the friable growth. I attempted to sew the mucous membrane and peritoneum together after the method of Martin, but could not accomplish it, and relied upon forceps instead. The vagina was packed with iodoform gauze around the forceps, and the patient put to bed under blankets and with hot bags placed upon her.

At the close of the operation the pulse was very

rapid and feeble, and shock was well marked. Upon recovering consciousness much pain was complained of, necessitating the administration of morphia. During the operation some ether got into the left eye, and this caused much discomfort, which was relieved by the instillation of a four per cent. solution of cocaine. The evening of the operation and the next morning the temperature remained normal, but on the evening of the second day it reached 101⅖°, and the next morning 101⅕°, dropping to 100⅘° on the evening of the third day. This transient rise of temperature was probably due to a localized peritonitis, as was evidenced by some abdominal tenderness and irritability of the bladder. The catch forceps were in about forty hours, and no hemorrhage followed their detachment and removal.

After the third day the temperature remained most of the time about 99½°, reaching normal on the tenth day. At first the urine was drawn, but once the patient was obliged to void her urine spontaneously, and afterward she continued to do so naturally. The pulse was quick and feeble prior to the operation, and has continued rather rapid since, ranging from about 120 during the first forty-eight hours down to 86 on the ninth day. The bladder was somewhat irritable at first, but soon became regular in its functions. Probably the most distressing feature of the case has been the formation of hardened feces, which were passed with difficulty and much pain. This constipation was probably due to the milk diet to which she was restricted. Another complication which was very much to be deplored was the formation of large sloughs from the hypodermatic injection of whiskey during the operation. The deep layer of iodoform gauze was not removed for a week, by which time it had become saturated and offensive. The wound by this time was reduced to a slit and was granulating nicely. The intestines were not to be seen. The dressings were removed at intervals of a few days, and the vagina irrigated. The discharge has been very slight from the beginning.

The patient sat up on the side of the bed for the first time on the fifteenth day. At this time a most unfortunate complication developed in the occurrence of erysipelas and cellulitis of the arm at the seat of an injection of whiskey. The arm became hot and painful, with much swelling, the temperature gradually increasing for four days until it reached 103°, and pulse 120. An abscess of considerable size was now discovered, and upon puncturing it a free discharge of pus took place with immediate relief of pain and a fall of temperature to 98⅘° by the next morning. The patient is still weak, more from the cellulitis than from the operation, but is able to sit up and to go from room to room, and I hope will soon be out of the house.[1]

This operation was delayed too long, and should have been performed when the disease was first discovered, but the physical condition of the patient did not justify such a severe operation at that time; and, moreover, the consent of the patient and her friends to the performance of hysterectomy was withheld.

1 MOUNT ROYAL TERRACE, BALTIMORE, MD.,
December 20, 1888.

[1] Since this paper was written the patient has been out riding.

A CASE OF HODGKIN'S DISEASE ACCOMPANIED WITH A POSSIBLE RESULTING PARAPLEGIA.

REPORTED BY LEWIS H. ADLER, JR., M.D.,
RESIDENT PHYSICIAN, UNIVERSITY HOSPITAL, PHILADELPHIA.

IN an article in Pepper's *System of Medicine*, Dr. Wm. Osler describes this disease as being characterized by progressive hyperplasia of the lymph glands, sometimes also of the spleen, with anæmia, and the development of secondary lymphatic growths in various parts of the body.

It has various synonyms; those deserving particular mention are pseudo-leukæmia, general lympho-adenoma, lympho-sarcoma, adenoid disease, and malignant lymphoma. It is also called Hodgkin's disease, after the physician who first studied and called the attention of the profession to it.

The case which I wish to describe is that of a married white woman, M. J. F., æt. twenty-six, a native of this State. She was admitted into the wards of the University Hospital August 31, 1888, under the care of Dr. H. C. Wood.

Dr. Joseph Leidy, Jr., was at that time Dr. Wood's resident, and from notes taken by him I glean the following as the patient's condition upon admission: She was unable to use her lower extremities; the muscles of the legs were wasted and flaccid; responded well to electricity (faradic current). Reflexes were good, possibly increased. Sensation unimpaired. There was a large bed-sore over the sacrum, and another commencing over the right trochanter major. Pressure over the spinal column elicited pain; particularly from the fourth to the sixth dorsal vertebræ. In the lumbar region a marked lateral curvature to the right was noticed.

Her family history, which I obtained, was good. No scrofula or specific trouble evident. Was always healthy up to time of marriage, which occurred when she was twenty-three years old. Said that "she had never taken a drop of medicine up to that date." Her husband and his family were all healthy, so far as I was able to ascertain. She menstruated at thirteen; was always regular except when pregnant. Since marriage has had two miscarriages; one at three months, the other one month sooner. Assigned as a reason for this trouble, heavy lifting.

Four months before admittance to hospital she was delivered of a healthy child at full term. Shortly after this pregnancy, the cervical glands only, and of the left side, became swollen and hard, but not painful, with no tendency at any time toward suppuration. She never was in perfect health after her first miscarriage, which happened six months after marriage. It left her not only very weak but exceedingly nervous. Under a physician's care she

improved greatly. She again became pregnant, and again miscarried, this time at the end of two months.

Her third pregnancy, which ended four months before coming to the hospital, resulted, as previously stated, in the birth of a fine, healthy, full-term, male child. When three months gone she felt as though she was about to abort again, but was put to bed and carefully nursed; which undoubtedly prevented a return of former occurrences.

Three weeks after this confinement she was taken suddenly with sharp pains in the dorsal region, which extended up the spinal column. A week later she noticed that her strength was deserting her, shown by becoming tired and exhausted without apparent cause. This condition of affairs grew rapidly worse, and in a few days she was unable to stand upon her feet. Her legs were both numb and painful, and power of moving same was soon entirely lost. At the end of nine weeks she had no control over contents of either bladder or bowels.

On September 15, 1888, I assumed Dr. Leidy's place as Dr. Wood's resident. A careful examination of the case at that time revealed the following condition of affairs: The patient was very anæmic looking, and had lost, as she stated, considerable flesh. Her tongue was pale, furred, and heavily coated; edges clean. There was a marked inequality of pupils of eyes. Also an otorrhœa of the left side. Upon the same side of neck there was an irregular mass of glands, hard to the touch, but not tender, about the size of an ordinary child's head. The right side had a few enlarged glands; in all, not larger than a pigeon's egg. The skin was free and movable over this region. In the left axilla there were several large lumps; none in the right side. The left arm was somewhat œdematous, possibly from pressure upon the axillary veins. The inguinal glands were slightly enlarged, but equally so upon both sides. No enlarged glands or tumors could be felt within the abdominal cavity. The spleen and liver were both normal in size. There was some œdema of the feet and ankles, which was attributed to the sluggish circulation. Examination of the heart revealed a low-pitched, soft systolic murmur over its base, which was undoubtedly anæmic in origin. The murmur was also accompanied by a venous hum in the neck. The pulse though rapid, was weak, varying from 90 to 130 per minute. The lungs were healthy, except over bases, where they were somewhat dull upon percussion, and respiratory sounds were feeble. There was fever present of an irregular, hectic type, which, during the last two weeks of the patient's stay in the house became continuous in character, with evening exacerbations.

From just above the umbilicus there was found to be complete loss of motion and sensation of all the parts of the body below. And, as in the case described by Dr. James H. Hutchinson (*Trans. of the College of Physicians of Philadelphia*, series 3, vol. i.), the line of separation between the parts where sensation was preserved and where it was lost was sharply defined by dragging a pin along the surface of the abdomen. Likewise there was a sense of constriction, as of a band, at the point separating the paralyzed from the sensitive portion of the body.

Unlike Dr. Hutchinson's case, there was in this patient a tendency to contraction, and spasmodic twitching of the muscles. They were not, however, very marked. The knee-jerk upon the right side was below normal; that upon the left side was about right. She complained constantly of headache and burning pain in the lower portion of the body, especially in the feet and toes—which were relieved by large doses of morphia.

The decubitus of patient was a curious one. She lay constantly with her knees bent and her legs drawn up. What significance to give this, except there be some meningeal trouble could not be determined.

The urine was examined and found to contain an excess of phosphates and urates, but no albumin. Specific gravity of 1025, and reaction acid. Examination of the blood, made for me by one of my colleagues in the hospital, Dr. Alfred C. Wood, showed the count of red blood-corpuscles to vary at different times from 3,500,000 to 2,500,000, the last estimate being the one made just before the patient left the house; she having been told that her case was hopeless, and her husband wishing her home.

No treatment proved of any use. To procure sleep and relieve pain, opiates constantly were resorted to, but no remedy did any good so far as the general disease was concerned.

She left the hospital November 23d, and died six days afterward. No post-mortem was allowed. It is more than likely that the paraplegia in this case resulted from a lymphoid tumor or tumors pressing upon the spinal cord, as in the case already alluded to of Dr. Hutchinson's, and in that of a similar case seen by Dr. William Osler, at Montreal.

The cause of the disease is a matter of conjecture, as it is in almost every other reported case. The otorrhœa, which Virchow believes generally precedes the disease when it starts in the neck, in this case followed it, showing that it was a sequence and not a cause of the trouble.

The curvature of the spine, previously mentioned, which existed in this case, was unquestionably due to disease of the vertebræ, a result of the general affection—for we know that in this trouble the bones are often found diseased.

41 NORTH TWELFTH STREET.

MEDICAL PROGRESS.

Naphthalin in Intestinal Catarrh.—DR. HOLSTI (whose work is mentioned in the *Nordiskt Mediciniskt Archiv*) has tried naphthalin for intestinal catarrh with foul-smelling secretions. The dose for adults was eight grains four or five times a day, but it should not be given for a longer time than from ten to fourteen days. For children of from one to two years old, he gave two to three grains four times a day. In all cases, both in adults and children, there was an improvement at the com-

mencement. Sometimes there was a relapse, notwithstanding the renewed use of the naphthalin. Dr. Holsti specially recommends it in severe chronic enteritis where other drugs have been employed without effect. He found no injurious effects from its use in adults; in one case—that of a child a year and a half old—the use of naphthalin in doses of two grains four times a day was followed by great anæmia, although the intestinal catarrh was much benefited. Hence Dr. Holsti advises care in the administration of naphthalin to children, especially when given for a lengthened period. He found it fail in two cases.—*Lancet*, December 22, 1888.

The Virulence of Tuberculous Sputum.—DR. DE TOMA, of Lesa (*Annali univ. di med. e chir.*, March, 1888), made a number of experiments to determine the virulence of tuberculous sputum, and obtained the following results:

1st. Tuberculous sputum excluded from the air and kept at a constant temperature of 68° F., retained its virulence up to the ninth or tenth day; and the tubercle bacillus, under the same conditions, up to the fourteenth or fifteenth day.

2d. Tuberculous sputum which had been exposed to the air retained its virulence from two to nine days, while the tubercle bacillus lived from six to fourteen days.

3d. Microbes from the mouth and nasal secretion which had found their way accidentally into the sputum, did not, as a rule, when inoculated, hinder the action of the tubercle bacillus, except when mixed with a large quantity of phlegm, in which case they developed more rapidly than the tubercle bacillus, and became on their own part an infectious medium.

4th. Decomposition destroyed the virulence of the sputum within three to nine days, and killed the tubercle bacillus within six to fourteen days.—*Centralbl. f. klin. med.*, Dec. 15, 1888.

Intermittent Hydronephrosis.—Under this heading, DR. LEOPOLD LANDAU, Professor of Gynecology at the University of Berlin, publishes four cases of a disease but little known (*Berlin. klinische Wochenschrift*, Nos. 47 and 48). The definition is limited to those cases in which the pelvis of the kidney varies, from time to time, between distention and emptiness, in the absence of other disease which might exhibit this symptom—for example, passage of renal calculus, malignant disease of the bladder, etc.

The symptoms described are more or less severe pain in the side, lasting from hours to days, and recurring at intervals, associated with nausea and vomiting, general gastric disturbance, cardialgia, etc. The flow of urine is scanty during, and profuse after the attack. The existence of a swelling which sometimes disappears may be known to the patient, or a hard, non-fluctuating tumor, separated from the liver by resonance, may be made out on palpation. As, after a time, the urinary elements of the fluid are reabsorbed, they may not be found by exploratory puncture, but the acidity of the fluid would be enough to fix the diagnosis. Dr. Landau maintains that spasm of the ureter alone would not be enough to account for the largely distended renal sac, and points out how the ureter may be occluded by torsion or tension, when the kidney is abnormally movable, or when pulled upon by prolapsed genitalia with cystocele, or when the ureter is inserted at a more acute angle. Thus, the pelvis is distended until the pressure is sufficient to overcome the obstruction. With each attack it loses elasticity, and dilates gradually into a large sac, which drags the kidney downward, thus aggravating the mechanical disadvantage of the contained fluid, for the ureter is inserted then at the top of the sac instead of at the bottom, and is also in greater measure pulled upon, twisted, or "kinked." Finally, neither the recumbent position nor manipulation may be able to effect evacuation, and the cyst becomes permanent and the kidney atrophies. Of the cases, one went on, after repeated attacks, to pyelitis, and is interesting from the fistulous opening then made in the side having persisted discharging clear urine for eight years, with but slight inconvenience to the patient. Two others showed a cessation of the symptoms during pregnancy—when the kidney was kept in position by the gravid uterus. One of them was relieved, on the recurrence of the attacks after confinement, by external pressure by means of an abdominal bandage. All the cases were of women from thirty to sixty years of age.—*British Medical Journal*, December 15, 1888.

Benzoate of Sodium in Diphtheria.—DR. BRANDEL, having treated a large number of cases of diphtheria with benzoate of sodium, reports his *modus operandi* as follows:

Internally. Administer every two hours, morning and night, a tablespoonful of the following:

℞.—Benzoate of sodium . . . ℥ss–℥jss.
Syrup of acaciæ . . . . ℥iij.—M.

Externally. Apply every hour, day and night, the following solution:

℞.—Benzoate of sodium . . . ℥iij.
Water . . . . . ℥v.—M.

Further: evaporate near the bed of the patient a mixture of phenic acid, eucalyptol, and oil of turpentine. The diet to consist of milk, the juice of meats, and cinchona or Malaga wine.

In itself, this treatment is not new, but its simplicity recommends it. Success is said to depend upon the purity of the benzoic acid used.—*Revue de Thérapeutique*, Dec. 13, 1888.

Determination of Albumin in Urine.—DR. SCHAUMAN, in *Zeitschrift für Analytische Chemie*, vol. xxvii. part 5, proposes a modification of the gravimetric method for the determination of albumin in urine. Instead of the ordinary paper filter, he uses a plug of cotton-wool freed from fatty matter, and pressed firmly into a glass tube drawn out to a narrow point. For this purpose a filter tube is adapted, as introduced by Allihn for the determination of sugar. This tube, with its cotton plug, is dried at 110°, and weighed. It is then fixed firmly by means of a cork, in a filter support, which is, in turn, connected with a filter pump. The albumin in a weighed quantity of urine is precipitated in a beaker by the addition of a small quantity of acetic acid, and heating for half an hour on the water bath. The clear supernatant liquid is first poured into the tube. The coagulum, which adheres rather firmly to the bottom of the beaker, is repeatedly washed with hot water, and the washings carefully

poured upon the cotton before the preciptated albumin is introduced. This is then washed with hot water, with the aid of a filter pump, until the liquid running out, no longer gives a chlorine reaction with silver nitrate. The tube is then closed at the wider end with a cork, perforated to admit a glass tube. It is then placed in a small rectangular drying box of sheet iron, provided on each of its two opposite sides with a circular aperture, into which the filter tube is inserted. The end having the perforated cork is connected with a calcium chloride tube and a washing bottle charged with sulphuric acid, whilst the drawn-out end is connected with an aspirator. For an hour a moderately rapid stream of dry air is drawn through the filter tube. The temperature in the drying box is gradually raised to 100°, and, after heating to this point for an hour, it is raised further to 110°, dried air being still drawn through in a moderately strong current. After heating for two hours at 110°, the tube is weighed and reweighed every half hour until the weight is constant.—*British. Med. Journ.*, December 22, 1888.

The Relative Power of Different Antiseptics.—DR. G. MARTENS describes in his work upon this subject the results obtained from the action of a large number of antiseptics upon pus-germs (staphylococcus pyogenes albus, aureus, citreus; streptococcus pyogenes). The experiments were made to determine the germ-destroying power, as well as the arrest-of-growth power of the various antiseptics; part of these proved to be germ-destroyers, while the action of others was either indifferent or negative.

In a solution of 1 : 10,000, iodine only was found efficacious in destroying pus-germs; iodoform was neither able to destroy the pus-germs, nor to hinder their growth; the same is true of iodide of potassium. Next to iodine, thymol was found to be the strongest antiseptic, destroying pus-germs in a solution of 1 : 5000 within one minute; the addition of a solution of 1 : 10,000 to agar-agar prevented the development of these cultures.

In a solution of 1 : 1000, the pus-germs were destroyed as follows: Within forty-five seconds by javelle water; within two minutes by nitrate of silver; within one minute by nitric acid; and only after the lapse of five minutes by muriatic acid. Sulphuric acid in the proportion of 1 : 100 within forty-five seconds. A sublimate solution, 1 : 1000, was destructive to the pus coccus in sixty minutes, while in a solution of 1 : 100 it acted instantaneously.

A solution of benzoic acid 1 : 500 acted within seven minutes; salicylic acid 1 : 300 acted within one to two minutes.

In solution of 1 : 100 chloride of iron acted within fifteen seconds; chlorinated lime within fifteen seconds; acidulated sulphate of potassium within thirty seconds. A five per cent. liquefied carbolic acid destroyed the pus-germs instantly; a three per cent. solution within fifteen seconds; while a one per cent. solution required from one to three minutes for operation. A one per cent. solution of permanganate of potassium only proved effective after the lapse of ten minutes. Chinoline, chloride of copper, resorcin, in a one per cent. solution, were slow in operating; acetate of aluminium, in a one per cent. and stronger solutions, requiring an entire day for action.

In dilutions of 2 : 100, acetic acid was destructive within ninety-five minutes; oil of turpentine, pure, immediately, while in dilutions of ten per cent., to three per cent. and one per cent., it proved less active.

In solutions of 5 : 100, chloride of zinc acted within forty-five seconds; a four per cent. solution of boracic acid required ten days, while borax was entirely inactive.

A ten per cent. solution of caustic potash destroyed the pus-germs within five minutes, while a fifteen per cent. solution proved effective within fifteen seconds. Nitrate of lead had no special antiseptic power; a ten per cent. acetate of copper solution required twenty-one hours; a chloride of calcium solution, twenty-eight hours; a citrate of iron solution, twenty-four hours; and antipyrin, ten days to destroy the pus-germs.

A fifty per cent. solution of cadmium sulphate destroyed the germs in one and a half minutes; lead acetate in fifteen hours, and acetate of sodium in ten days.

Fifty per cent. alcohol solutions proved effective in ten minutes; cold saturated solution of nitrate of bismuth was effective in one hour and forty minutes; limewater, in twenty hours; sal-ammoniac, in twenty-four hours; aqua ammoniæ, in six days; sulphite of ammonium, after twenty-four hours.

The following preparations proved ineffective: Iodide of potassium, bromide of potassium, nitrate of potassium, caustic potash, pearlash, chloride of sodium, sulphate of sodium, borax, hyposulphite of sodium, carbonate of ammonium, sulphate of zinc, oxide of copper, and others.—*Centralbl. für klin. med.*, Dec. 15, 1888.

Toxic Symptoms after the Subcutaneous Injection of Cocaine: Amyl Nitrite as an Antidote.—UNKOWSKY (*Vrach*, No. 4, 1888) has frequently noticed slowing of the pulse, dizziness, dyspnœa, paleness of the skin and mucous membranes, general weakness and, at times, unconsciousness after the subcutaneous injection of one to two syringefuls (15 to 30 minims) of a four per cent. solution of cocaine ($\frac{3}{5}$ to $1\frac{1}{4}$ gr.) for minor operations; these symptoms all usually disappeared within five or ten minutes. The author at first, thought that the manifestations were not dependent on the small amount of cocaine, but rather upon nervous excitement and the fear of operation. The following case, however, demonstrates the toxic influence of even relatively small doses of cocaine subcutaneously administered. Two syringefuls (30 minims) of a four per cent. solution were injected under the skin of the scrotum of a robust, fifty-six-year old man, with hydrocele. In a few minutes there were great restlessness, severe oppressive pain in the back, particularly in the lumbar region, relieved somewhat by friction of the back, then there was striking pallor of the countenance and the visible mucous membranes, dizziness, dryness of the mouth and throat, dyspnœa, pulse retarded and small; the patient complained that he could not see; everything appeared uniformly white to him; finally, there were general weakness and complete inability to move the limbs, as in chloroform narcosis. The pain in the back and the difficulty of breathing occurred in paroxysms, the attack, with the general collapse, at times threatening life.

During such attacks amyl nitrite was given by inhalation until the dyspnœa diminished and the pallor disappeared. An hour was thus spent. the patient inhaling about fifteen minims of amyl nitrite and receiving three syringefuls of ether by subcutaneous injection. Gradually the manifestations disappeared and the operation was proceeded with, complete insensibility to four per

cent. solutions of carbolic acid, to the passage of the needle, etc., existing and with complete inability to move the extremities. A half-hour later none of the symptoms remained. The author reports another case, in which one hour after the injection of a half syringeful (7½ minims) of a twenty per cent. solution (1½ gr. of cocaine) under the gum of the mouth, psychical disturbances occurred: and in still another, six hours after the injection of a syringeful of a four per cent. solution in the cheek, mild symptoms arose similar to those described.—*Therapeutische Monatshefte*, October, 1888.

β-Naphthol in Enteric Fever.—From a careful clinical study of the use of β-naphthol in typhoid fever, DR. J. MICHELL CLARKE, of London, draws the following conclusions:

1. That the production of intestinal antisepsis is a rational mode of treatment of enteric fever, and that β-naphthol is a safe and tolerably efficient agent for this end.

2. That by its use in the above cases the duration of the disease was shortened, and the intensity of the symptoms directly arising from profound disturbance in the alimentary canal was lessened.

3. That the tendency to the occurrence of splenic enlargement, albuminuria, and of secondary complications such as boils, abscesses, etc., of purulent infective origin, is diminished.

4. That complete convalescence is more speedily and satisfactorily attained: and that there is less risk of a propagation of the disease to others.

Finally, we must bear in mind that in some patients naphthol may excite so much gastric disturbance as to prevent its use.

β-naphthol was administered suspended in milk, and a small quantity of pure milk was taken after the dose. The doses must be administered frequently, in order to keep up a constant effect, and small doses have also the advantage of not giving rise to the pungent after-taste in the throat that naphthol is apt to produce. To adults it may be administered in gelatine capsules, or the following formula, which seems the most satisfactory after several trials, may be made use of:

℞.—β-naphthol	. . . . .	gr. xx.
Tr. aurantii	. . . . .	℥ij.
Syr. limonis	. . . . .	℥ss.
Mucilaginis tragacanthi	. .	℥iij.
Aquæ	. . . . .	ad ℥vj.

Dose, ℥j.

Taste, however, is practically abolished in most cases of enteric fever, and the patients to whom it was given in milk made no complaint on this score.

Out of seven cases, four—of whom two were boys of twelve years—took the drug in doses of three and a quarter grains every two hours during the whole course of the disease, until the temperature remained normal for five or six days; one boy, aged ten, took gr. iss instead of gr. iij doses.

Whilst giving naphthol it is also advisable to control the pyrexia that necessarily occurs in the course of enteric fever, and so prevent the damaging effects on the tissues and organs of the body of a long-continued high temperature; we should, therefore, together with naphthol administer an antipyretic, preferably perhaps antifebrin or phenacetin, whenever the temperature rises beyond a certain height, say, 102° F.—*The Practitioner*, December, 1888.

External Application of Chloral Hydrate in Night-sweats.—DR. NICOLAI (*Gazette Médicale*) has obtained very favorable results from the use of chloral hydrate in the night-sweats of phthisis. Every night before retiring the entire body of the patient was sponged with the following:

℞—Chloral hydrate	. . .	℥ij.
Alcohol Water	. . . .	āā ℥iij.—M.

Should this not suffice, the patient's night-dress is saturated with this solution, then allowed to dry, and worn.

This mode of treatment also gave excellent results in the night-sweats of children the result of phthisis. Two or three of these spongings will generally suffice to check a sweating which has persisted for two or three weeks.—*Bull. Thérapeutique*, Dec. 13, 1888.

Ammonium Sulpho-ichthyolicum in Erysipelas.—DR. W. L. SCHADKEWITSCH (*Medizinskoje obosrenje*, 1888, No. 12) has found equal parts of ammonium sulpho-ichthyolicum and fat to be an excellent remedy in the treatment of erysipelas, in which disease it limited the pain and duration of the attack.—*Centralbl. f. Chirurgie*, Dec. 15, 1888.

Poisoning by Antifebrine.—A bookbinder, aged thirty-eight years, obtained thirty grains of antifebrine from a druggist in Berlin for a headache, and, after twenty-four hours, thirty grains more, each quantity to be taken at one dose. A quarter of an hour after taking the second dose, the patient experienced great depression, with cold sweats, vertigo, anxiety, and heavy palpitation of the heart, with small and frequent pulse. The face and hands soon became dark and bluish. After the administration of some black coffee and castor oil, and the application of a mustard plaster to the abdomen, the blue color disappeared; by degrees the other symptoms followed, except the faintness, which lasted several days.—*Apoth. Zeitg.*

Salol in Children's Diseases.—DR. DEMME has lately published his experience of salol in children. He has used it in four cases of articular rheumatism, two of acute endocarditis, two of vesical catarrh, and also as an external application in two cases of burn. Two of the patients, aged eight and thirteen, were suffering from acute rheumatic polyarthritis. Forty grains of salol were administered in twenty-four hours, in divided doses. The doses were continued during five days in one case, and seven days in the other. When the temperature fell, the daily dose was reduced to twenty-four grains. The effects of the salol were not rapid, but there was no relapse, and the affection only lasted fifteen to sixteen days. Fifty-eight grains of salol were administered at intervals to a girl of seven, suffering from rheumatism. The temperature fell from 39.8° C. (102.9° F.) to 37.2° C. (98.8° F.) in forty-eight hours, and the pain and swelling in the feet, right knee, and left elbow were considerably diminished. In the case of another little patient of nine, the results were not so favorable, and

the salol administered as an emollient or in a lozenge, caused vomiting in from ten to fifteen minutes. A double dose, administered in the yolk of an egg, produced general urticaria in eight or ten hours, without having any effect on the fever or the state of the articulations. Salicylate of soda was substituted, and some improvement followed, but the eruption returned. The patient recovered eight days afterward, but had a relapse. Fifty-eight grains of antipyrin were then administered for four days, at the end of which the patient was completely cured.

In endocarditis, salol gave good results if the action of the pulse was modified by digitalin. In a case of cystitis caused by cantharides, salol also proved beneficial. Daily doses of from fifteen to twenty-four grains soothed the pain, increased diuresis, and caused the alkaline reaction and the muco-pus in the urine to disappear. Toward the end of the treatment the urine assumed a greenish-brown hue, resembling that produced by carbolic acid.—*British Med. Journ.*, December 22, 1888.

The Use of Defibrinated Blood in Chlorosis.—DR. BLONKVAJEFF (*Gaz. clin. de Botkin; Riform. Med.*, No. 251, 1888) undertook a number of clinical experiments to study the therapeutic value of defibrinated blood. Thirty-one patients in various stages of chlorosis were given, twice daily, from two to four ounces of defibrinated calf's blood. The first dose (at noon) was taken in the fresh state, and the second dose, which in order not to putrefy had to be frozen, was taken at seven o'clock. Calf's blood is not so disagreeable to the taste as that of the ox or dog; according to the statement made by some of the patients, it is pleasanter to the taste than many of the iron preparations. Only rarely did the patients complain of a sense of repugnance, and that only at the beginning of the treatment. Frozen blood has no taste at all, but when dissolved it was found less agreeable than fresh blood.

The results of the treatment were the following:

1. Upon the temperature. With patients in whom the temperature was slightly elevated, a return to the normal was noticed after a few days of treatment. The greater number of patients showed a subnormal temperature, which, under treatment, gradually rose to the physiological height.

2. The pulse, at first increased in frequency, became by degrees slower and rhythmical, and retained these properties no matter what position the patient assumed.

3. The dyspnœa disappeared toward the end of the treatment. Patients who at the beginning of the treatment were easily fatigued on mounting stairs, could, toward the end, run up and down, walk briskly, and dance without effort.

4. The body-weight of the patients increased.

5. The appetite increased; the patients slept better and felt stronger.

6. The color of the skin assumed a healthy hue from the start.

7. Headaches disappeared; the same was noticeable of other anæmic symptoms, such as toothache, lumbago, œdema of the face and legs, and perspirations, etc. All nervous excitement abated.

8. The bowel action became more regular; constipation was never produced; and even those patients suffering from diarrhœa could take the defibrinated blood, of course only in small doses.

9. The blood of the patients gained in hæmoglobin and red blood-corpuscles.

10. The quantity of urine and the chlorides therein contained were increased.—*Centralbl. f. d. ges. Therapie*, December, 1888.

Carbolic Acid in Palpebral Affections.—DR. SÉDAN (*Recueil d'Ophtalmologie*, 1888) advocates the following: Take six drachms of cocoa-leaves, eight ounces of water, and fifteen grains carbolic acid; make a decoction. Apply with an ordinary perfume vaporizer, every half hour, each application lasting from five to six minutes. He claims to have obtained better results with this, than with any other treatment. These applications produce a resolution of the inflammatory condition, a suppression of the insupportable itching, and almost complete anæsthesia. In treating sensitive eyes, it would be well to interpose a layer of cheese-cloth before applying the spray.—*Revue de Thérapeutique*, Dec. 15, 1888.

The Treatment of Digestive Disorders in Infants.—At the clinic of DR. ESCHERICH the stomach-pump plays a most important part; especially in stomach affections of infants, in which its application has been followed by good results. Of medicines, Dr. Escherich often uses salicylate of bismuth, the administration of which is preceded by small doses of calomel (three-quarters of a grain being the maximum dose) in order to obtain a slight disinfectant action upon the mucous membrane of the intestinal tract. Milk is entirely withheld, and in its place a diet is given from which all traces of sugar are excluded. Thus the white of an egg with Russian tea—the last as a light stimulant and astringent—forms a pleasant as well as a nourishing potion. Besides this, beef extracts, or calf soup, an alkaline reagent, or peptonized foods are permissible. After two or three days small potions of sterilized milk are again administered.—*Correspondenzblatt für Schweiz. Arzte*, December 15, 1888.

Lantanin, a New Antipyretic.—DRS. ROUIZA and NEGRITA, of Lima, obtained from the Brazilian Lantana an alkaloid called *lantanin*, which acts upon the circulation like quinine; besides lowering the temperature, it has the advantage over quinine of being tolerated by the most delicate stomach. Its antipyretic action has been established in cases of intermittent fever, in which the sulphate of quinine proved useless. It would seem that the fall of temperature was due to the specific action which this drug has over the existing morbid condition.

It can be administered in pills of two grains each, one pill at a dose, giving as much as thirty grains in twenty-four hours.

To prove effective the administration should be made directly after a paroxysm, which ordinarily does not reappear. Some difficulty might be encountered in employing a tincture of lantana, as no corrective has thus far been found for its intense bitterness.—*Revue de Thérapeutique*, December 15, 1888.

For Chapped Nipples.—DR. MONTI advises to cover the fissures with a layer of traumaticin (ten parts gutta-percha dissolved in eighty parts of chloroform), which covering, thus formed, will protect the nipples against the action of the infant's saliva.—*Gazette de Gynècologie*, December 15, 1888.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JANUARY 12, 1889.

ATROPHY OF THE SECRETING GLANDS OF THE STOMACH.

THE obscurity which always surrounds the diagnosis of atrophy of the gastric mucosa has been brought prominently into notice by the death of a well-known physician of this city, in whose case this diagnosis was accurately made—post-mortem.

There is no single symptom common to all cases of this disease, and this arises from the fact that the function of the stomach is exceedingly complex, and may be, to a large extent, supplemented by that of the intestine. As is well known, a certain number of cases of atrophy of the gastric mucosa present the clinical picture of pernicious anæmia, whereas others —and these form the majority—are not associated with this degeneration of the blood. The explanation of this perplexing anomaly given by LITTEN in a recent number of the *Deutsche medicinische Wochenschrift*, is probably correct, viz.: that in those cases in which profound anæmia is absent, the motor power of the stomach is sufficient to propel its contents, in physiological time, into the duodenum.

Although no one of the numerous symptoms of gastric atrophy is diagnostic, the entire group, taken in connection with a chemical examination of the gastric secretions, suffice to render the diagnosis almost certain. The more difficult question whether the atrophy exists alone as the terminal stage of a chronic catarrh, or as an extension from a carcinomatous deposit, is to be decided chiefly by the clinical history and the age of the patient. The data upon which is based the diagnosis of atrophy, are cardialgia, the absence of mucus and of hydrochloric acid from the gastric secretions, and the diminution or complete loss of the functions of digesting albumin and of curdling milk. In addition, the absorbent power of the stomach may be impaired, as observed by Litten, who was unable to detect iodide of potassium in the urine of patients with gastric atrophy until several hours after it had been swallowed.

JAWORSKI (*Verhandlungen des* VII. *Congresses für innere Medicin*) believes the absence of pepsin and milk-curdling ferment (Labferment) to be the distinguishing marks of gastric atrophy. The secretion of these enzymes is stimulated by the injection into the fasting stomach of a weak solution ($\frac{1}{10}$ per cent.) of hydrochloric acid. Two hundred cubic centimetres of this solution are injected into the stomach, allowed to remain half an hour, then withdrawn and tested with reference to their digestive and milk-curdling power. If these are absent, the diagnosis of gastric atrophy is justified.

Studies of the milk-curdling ferment, with a view to determine the diagnostic significance of its presence or absence, have been recently made by JOHNSON, of Stockholm, BOAS, and KLEMPERER, the result of which is that its importance in this respect is but slight. It is agreed that this enzyme is absent in most cases of chronic catarrh of the stomach, in carcinoma, and in atrophy, *i. e.*, in just those affections in which hydrochloric acid is usually absent from the gastric secretions. The fact is that its diagnostic significance is precisely similar to that of hydrochloric acid, upon which it depends for its very existence. The gastric tubules do not secrete the "labenzyme" itself, but a "proënzyme," or "labzymogen," which is converted into the labferment by means of hydrochloric acid.

From the foregoing remarks it is evident that the diagnosis of gastric atrophy, like that of other obscure affections of the stomach, is largely chemical; and although certainty in diagnosis has not yet been attained by such methods, there is good reason to believe that they are surely leading to it.

THE MUNICIPAL AND MEDICAL CARE OF THE POOR.

THE relation between the medical profession and the State has been as fertile a source of discussion as the relations of church and State. "Paternal

governments" subsidize large hospitals and asylums, and support their officers. This is well exemplified by Austria, which receives the woman pregnant with a foundling child, cares for her, and adopts and for a time supports her offspring. However such a policy may be regarded from the standpoint of the moralist, a direct benefit to science results in the collection of vast material for clinical observation available to competent medical scientists whose services to the State are directly recognized.

Under a republic the problem becomes more difficult. The voter is King, even though dependent on his fellow-citizens, and unless criminal is susceptible to government control in a limited degree only. No man can be taken from his dwelling, which is his castle, to a hospital against his will. Clinical material is to be obtained with comparative difficulty, and competition in the control of the sick poor results in establishing dispensaries and hospitals which are private enterprises. This commercialism in medicine is the logical result of the present relations of the profession and the government, municipal or general, and in process of time will undoubtedly be changed.

Medical men interested in science, in medical education, and the good of the community have a duty in improving these conditions which should not be slighted. The functions of the government as a promoter of progress in medical science should be largely supported. Municipal hospitals, infirmaries, and almshouses should be brought to a high standard of excellence, and thus made to coöperate in increasing medical knowledge. While the citizen of a republic may not be as completely in the hands of the State as the monarchist, yet American laws supported by intelligent public opinion exercise a wise and humane control over the poor. This control is best exercised by discrimination regarding the needs of the individual case. The acute and chronic disability should be promptly recognized, and public funds used quite differently in dealing with the two. For the former the hospital is indicated, where proper medical care, aided by the best known appliances, will return the patient to self-support as quickly as possible and at the least expense to the State, having contributed clinical observations to medical science. For the chronic and disabled, a place of abode should be provided where, in proportion to the strength of each, sufficient labor may be performed to reduce the cost of maintenance.

Experience in other cities has shown that a city hospital, as perfectly equipped as possible, and an almshouse and farm, removed a convenient distance from the town, furnish the best method of caring for the poor. The almshouse should have sufficient land for a farm on which inmates may labor in suitable weather. The best interests of science and good government are, in a measure, defeated when a city hospital is allowed to remain so crowded with the chronically disabled as to tax the resources provided for acute cases. Such is now the case with the Philadelphia Hospital, one of the oldest and largest in the country. Under the efforts of the Board of Charities and its medical staff, with its admirable training school for nurses, it has been brought to a high grade of efficiency as a hospital, affording facilities for the scientific treatment of disease and available for medical education. It has labored under the disadvantage of overcrowding by indiscriminate inmates. A move is now on foot to correct this condition by the removal of those suitable to an almshouse, leaving the hospital to continue unimpeded in its growth and development.

A similar experience is not uncommon in American cities, and it is the duty of the profession to join hands with the municipality in mutually furthering medical science and good government.

The United States Commission for the investigation of hog cholera have concluded their labors in Baltimore for the present and have gone to South Carolina. The Commission is composed of three members—Professor Shakespeare, of the University of Pennsylvania, Chairman; Dr. B. M. Bolton, formerly of Johns Hopkins University; and Professor Burrill, of the Botanical Department of the State Agricultural College of Illinois.

The recent news from Hayti shows that the U. S. ship "Yantic" has been ordered home in consequence of yellow fever having boarded her. The "Yantic," being of wood, will hereafter have a very restricted sphere of usefulness. The "Boston," iron cruiser, having been stripped of all her contents, will this week be burned out with sulphur by the barrel. The extent of the fever outbreak on the "Yantic" is not known, but it is believed that she has never been infected hitherto.

The Trustees of the University of Pennsylvania at their meeting held this week transferred Dr. James Tyson from the Chair of General Pathology and Morbid Anatomy to that of Clinical Medicine, and

Dr. John Ashhurst to that of Surgery. The appointments to the vacant Chairs of Pathology and Clinical Surgery will probably be made next month.

AT the annual meeting of the College of Physicians of Philadelphia, held last week, Dr. D. Hayes Agnew was elected President for the current year.

DR. THEOPHILUS PARVIN has been elected President of the Obstetrical Society of Philadelphia.

AT the annual meeting of the Kings County Medical Association, held on the 2d inst., Edward R. Squibb, M.D., was chosen President for the ensuing year. The Association has found permanent quarters at the new Hoagland Laboratory.

THE German government maintains a paternal oversight of the workmen upon the public works. The *Engineering Record*, for the 8th ult., shows that a considerable sanitary control is imposed upon the contractors of the great Northeast Sea Canal, connecting the Baltic with the North Sea, both as to the selection of the workmen and as to their treatment at the works and in the sheds or barracks.

The canal commission is obliged to keep up at the larger sheds a continuous series of instructions in what is termed the "Samaritan Service"—a new but very significant expression—upon which instructions all the laborers may, in turn, be required to attend by the shed-inspectors. A fire-drill, similar to that which is seen on ocean-going steamers, is a part of the scheme. The cost of these lessons is borne by the governmental commission having oversight of the laborers.

In many of the large public works in this country there has been a general disregard of the sanitary rights of the workman; and we know of some instances where the loss of life has been wasteful in the extreme. We commend to our philanthropists and to the "lovers of the workingman," a careful study of this German innovation, "the Samaritan service," as a means of education in presence of mind, self-help, and as a measure conservative of his sanitary rights.

One other salutary provision which exists in this German oversight of the workman, is the exclusion of contagious and unsightly disease from the sheds, and this is accomplished by means of a medical examiner whose decision is final in regard to the admission of all new men upon the works.

THE self-prescriber has already heard of sulphonal and is taking it in the maximum dose in order to produce sleep. He is also recommending it to his friends who cannot sleep, in doses which are not free from danger. The popular use of antipyrin, which has been going on for over a year, has done no little injury; we have known thirty grains to be advised by one layman to another as an initial dose. We predict that the time must soon come, through the multiplication of these potent neurotic medicines, when physicians will insist upon the non-renewal of these potent prescriptions by pharmacists without a written order. It seems to us quite probable that we have simply arrived at the threshold of this department of chemical work, and that the profession will be compelled to throw additional safeguards around the unauthorized use of these powerful agents.

THE educational departments of various governments present reports showing the number of students who matriculate in the colleges, universities, and seminaries. In Germany the number is 24,000; in Great Britain 26,000; in this country 90,000. These figures when compared with the estimated populations of the same countries, enable us to make the following ratios: in Germany there are 53 students in 100,000 inhabitants; in Great Britain there are 46; while in the United States there are not less than 150. The demands of the standing armies of most European nations must shut out a great many male students from advanced collegiate pursuits. Militarism hampers the higher education.

THE death of Dr. Joseph L. Bodine, of Trenton, New Jersey, at the early age of forty-nine, robs the Medical Society of that State of a valuable member. He died January 2d. He was a graduate of the University of Pennsylvania, Class of '65. He had formerly been a Commissioner of the Sinking Fund for New Jersey.

REVIEWS.

A PRACTICAL TEXT-BOOK OF THE DISEASES OF WOMEN. By ARTHUR H. N. LEWERS, M.D. Lond., M.R.C.P. Lond., etc. Crown 8vo. pp. 400. London: H. K. Lewis, 1888.

THE most convenient handbook for the student, or to refresh the memory of the busy practitioner, which we have seen. Thoroughly up to modern knowledge, it contains no superfluous matter, but clinical points of importance are clearly illustrated. Some peculiarities of English practice appear: iodine water is used as an

antiseptic, and the practical value of electricity in treating pelvic exudates and neuralgias is not fully recognized. Modern pathology and operations are concisely stated; instruments are described: symptoms noted; and even the rest cure receives mention. The book is a veritable *multum in parvo*, and of decided utility.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN OBSTETRICS AND GYNECOLOGY.

JOSEPH JANVRIN, M.D., CHAIRMAN.

Stated Meeting, December 27, 1888.

DR. JAMES P. TUTTLE reported a

CASE OF EXTRA-UTERINE PREGNANCY IN WHICH THE FŒTUS WAS DELIVERED AT FOUR MONTHS PER RECTUM.

There is no subject of greater interest now before the profession, he said, than the diagnosis and management of ectopic gestation, and aside from its unusual termination, the case in question would, he thought, suggest some of the difficulties, not to say impossibilties of diagnosis, and would seem to illustrate the complications of certain methods of treatment advocated at the present day:

The patient was a lady thirty-five years of age, who had been married eleven years, but never was pregnant. For several years she had been treated by various methods for "falling of the womb." The menses had been generally regular, but several times had been delayed or omitted, without causing any inconvenience. Dr. Tuttle was called to see her on March 26, 1888. Her last two periods occurred about the proper time, though the flow was less free and of shorter duration than usual. She missed entirely her period due on March 13th, a circumstance which she attributed to exposure to the blizzard-weather of that date. She had always had a delicate stomach, and for some time past she had been troubled with nausea and loss of appetite.

Digital examinations showed the uterus to be slightly enlarged, well down, and apparently retroverted, or with posterior mural fibroid. The use of the sound was contra-indicated on account of the possible existence of pregnancy. There were great periuterine tenderness and great heat about the parts. The right ovary could be made out with difficulty, but was found to be enlarged and tender. The left could not be felt. The diagnosis made was pelvic cellulitis and ovaritis of right side; possible pregnancy.

Tho days later he saw the patient during a paroxysm of pain which was referred entirely to the rectum. It was due apparently to a spasm of the sphincter of that organ, and was promptly relieved by cold applications, and lifting up digitally what he supposed to be a large retroflexed and gravid uterus. An examination under anæsthesia was refused, and the patient, who was not disposed to accept the theory that she was pregnant, requested that she should be treated with electricity, which she said had been formerly successfully used in her uterine troubles. Believing that this was not the proper method to be pursued in the case, he surrendered her to an electro-therapeutist of the eclectic school, who had treated her before.

On April 23d, Dr. Tuttle was again requested to take charge of the case. The patient was then very weak, and unable to retain anything on her stomach. Pulse 120, temperature 101°. As the instruments used in the electrical treatment had been passed within the uterus, the diagnosis of pregnancy had been disposed of. She said she was still flowing from a menstrual period which had come on after an electrical *seance* several days before, and therefore an examination was deferred until a later date. He afterward learned that after this *seance* she had had a severe hemorrhage, lasting for several hours. At the time, she told him that she had had a severe and painful menstrual period lasting six days, during which she had passed large pieces of black blood, and leaving a slight flow, which still continued. Altogether the flow lasted six weeks, and this led him to believe that an abortion had been produced, and an islet of placenta left adherent.

Two days later the patient was in a much better general condition, and an examination was made, revealing the following condition: Continued vaginal heat and tenderness in peri-uterine pelvic tissues, uterus enlarged to five inches. slightly movable, in fair position, inclined somewhat to the right side. A large, round, hard tumor was between the uterus and rectum, not particularly painful on manipulation; closely attached to the uterus and movable with the latter, and to about the same extent. It presented the symptoms and feeling of a fibroid or possibly a hæmatoma.

The hot douche, boroglyceride tampons, and general constitutional remedies were employed for some weeks with fairly good results, and the patient believed that she was getting well. In spite of Dr. Tuttle's protests, she continued to attend to household duties, going to market, etc., and even furnishing a new flat, to which she moved during this time. On June 1st, his note was as follows: Has had continued slight flow of blood from uterus for past three weeks, in spite of local application of astringents, and administration of ergot and gallic acid. The dull curette does not find any vegetations, and the lining is smooth. Tumor does not seem to grow in size, but is sagging down in sacral fossa, causing retroversion and difficulty in stools, due to pressure on rectum, and commencing hemorrhoids. Injected ʒss ferri sulph. into cavity of uterus, and several large tampons inserted during the knee-breast position, with the idea of raising the tumor, if possible, above the pelvic brim.

The hemorrhage finally ceased altogether, and on June 25th he found that the tumor had sunken considerably lower and presented sensations of slight softening or breaking down. He proposed to put an aspirating needle into it in a day or two, but the next day he was hastily summoned to the house. where he found Dr. Harvie Dew engaged in delivering a fœtus from the rectum of the patient; severe griping and intense pain having followed the use of a cathartic the night before. He had been called after the feet had presented at the anus, and the delivery was accomplished without difficulty. The rent in the wall of the rectum was perpendicular in direction, and as straight and clean-cut as if done with a knife. It was two and a quarter inches in length, and located on the left posterior aspect of the gut about two or two and a half inches from the anus. The

cord was intact, but was atrophied and became detached from the placenta by the slight traction required in using it as a guide in reaching the latter. The placenta not following the child, the patient was etherized and an attempt made to remove it. It was firmly adherent, however, and the little manipulation ventured upon brought on arterial hemorrhage to such an extent that it was decided that it would be unwise to use any force on account of the weak condition of the patient. The cavity was therefore tamponed in the hope that the placenta would attach itself, or degenerate and come away gradually. By the time this had been accomplished the patient had an alarming failure of respiration, and artificial respiration had to be resorted to to keep her alive. Under hypodermatic injections of stimulants, hot packs, etc., she revived, and in the course of two or three hours was feeling quite comfortable, with a temperature of 99°, and pulse 140.

The patient continued very weak but suffered little pain. On June 28th the placenta was found plugged tightly in the rent; but the slight attempt to remove it brought on a condition of extreme shock, and it was decided not to interfere with it in her present state. About 7 A. M., on July 1st, she complained of a sinking sensation, and had Dr. Tuttle summoned. On reaching the bedside he at once recognized that she was sinking from hemorrhage, although he found the placenta still plugged into the rent in the rectal wall, and no blood was escaping into the rectum. All efforts to save her failed, and she died in about an hour. As her last request was that no autopsy should be made, the attachment of the placenta remained uncertain, but he thought it probable that it was to the left tube or ovary, from the absence of the latter in its accustomed place, and from the position of the placenta to the left of the median line.

It was to be observed, he said, that the patient had no definite symptoms of rupture of the tube or hemorrhage therefrom, while she was under his care. He, therefore, judged that the cyst containing the child had probably burst into the cavity or folds of the broad ligament, as in some cases mentioned by Lawson Tait; and believed that but for the severe straining produced by her self-inflicted catharsis, it would have proceeded to the usual result in such cases, viz.: decomposition, abscess formation, and its concomitant constitutional symptoms, rupture, and discharge through the rectum or vagina. It was also noticeable that there were never any of those colicky pains usually met with in ectopic gestation, and that the symptoms of pregnancy had almost totally disappeared when she came into his hands a second time. In fact, the symptoms after this were those of a simple uterine fibroid or hæmatoma, indicating that the death of the fœtus had taken place before this time; and it was his opinion that this had been brought about by the electrical treatment employed. The case was of interest, he thought, therefore, as illustrating the dangers of electricity in extra-uterine pregnancy (which had been so long advised by some of the best gynecologists), and the darkness in which we were afterward left. The fœtus was in a good, but not perfect state of preservation; and Dr. Tuttle said that while numerous instances are on record of disintegrated fœtuses being delivered out of abscess sacs through the rectum or vagina, he had failed to find in the literature of the subject a single case in which, as here, the delivery of the fœtus occurred intact.

DR. R. A. MURRAY presented

SPECIMENS FROM A CASE OF HÆMATOMA OF BOTH OVARIES.

In this case extra-uterine pregnancy was suspected; but no evidences of its existence could be detected. Pyosalpinx was found in addition to hæmatoma, in connection with one of the ovaries.

DR. HENRY C. COE read a paper on

THE IMMEDIATE APPLICATION OF FORCEPS TO THE AFTER-COMING HEAD IN CASES OF VERSION WITH PARTIAL DILATATION OF THE OS.

He said he desired to call attention to a single condition in which the forceps should be at once used in cases of version, and would not be understood as advising their general use after version, or even the immediate delivery of the child. The following illustrative cases were cited:

CASE I.—Primipara, æt. thirty-five, slight contraction of the anterior conjugate. Labor induced near term from albuminuria and threatened eclampsia. The patient was very anxious for a living child. The head was grasped by the cervix, and could not be extracted until the forceps were applied; when it was readily delivered, but too late to save the child. The perineum was torn through the sphincter, but healed with primary suture.

CASE II.—Multipara, æt. thirty-five. Several dead children had been previously delivered by forceps applied high up, and she greatly desired to have a living child. There was slight narrowing of the anterior conjugate diameter. Version was performed; the head being arrested by the partly dilated cervix. The forceps were applied after vain attempts at manual extraction, and the child rapidly delivered; but it could not be resuscitated. In this case there was no laceration of the perineum.

CASE III.—Primipara, æt. sixteen. There was great rigidity of the soft parts. Eclampsia of unusually severe type occurred, and labor was induced. Version was performed, and the head was arrested, as in the previous case. Considerable time was wasted in manual extraction, and it was finally delivered with the forceps. The child was dead. Laceration nearly through the sphincter; healed with primary suture.

CASE IV.—Multipara, æt. thirty-eight. Hydramnios and fatty heart. Labor was induced near term. Atony of the uterus and serious cardiac disturbance occurred, and the fœtal heart was irregular in action. Version was resorted to. The head was grasped by the cervix, and the forceps were applied after a loss of several minutes. The head was large and unyielding, and the fontanelles were found to be nearly closed. The child was resuscitated, but died in convulsions a few hours later. There was a superficial tear of the perineum.

In each case the mother made a perfect recovery. From the results met with in these cases Dr. Coe inferred that many children might be saved under such circumstances by immediate application of the forceps. The reduction of infant mortality, he said, was especially important in private practice, and it was just the class of patients in whom we were obliged to perform version and extraction, who were most anxious to have living children. We must not allow our ideas as to the small importance of the child's life, imbibed in our hospital service, to influence us in private cases.

The application of the forceps did not present special difficulties. The perineum might be badly torn, or the cervix might be lacerated, in consequence of the rapid delivery; but patients would gladly overlook such lesions if the child's life was saved by the physician's prompt action, especially if former children had not survived. In conclusion, he called attention to the fact that in the cases reported (two of which were in private practice), the operator had had skilled assistants and nurses, who possessed experience in this class of cases; and yet had been unsuccessful. Under similar circumstances he would not lose a moment in attempts at manual extraction; but would apply the forceps as soon as he recognized the fact that the constricting cervix did not yield.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, December 12, 1888.

THE PRESIDENT, J. SOLIS-COHEN, M.D., IN THE CHAIR.

DR. JOHN H. PACKARD read a paper on

NOTES OF A SUCCESSFUL CASE OF LAPAROTOMY FOR INJURY BY A CIRCULAR SAW.

Charles B., aged twelve, was brought to the Pennsylvania Hospital, September 24, 1888, having fallen against a circular saw in rapid motion. The accident occurred about one mile from the hospital. On admission, the ascending colon and about two feet of the small intestine were protruding from a wound four inches or more in length, nearly vertical, on the right side of the belly, some two inches from the middle line. The mass was tightly grasped in the wound, so that access of air to the peritoneal cavity was prevented. The boy was in a condition of marked but not excessive collapse. He was etherized, and the parts antiseptically cleansed. The bowel was then carefully examined. Three wounds of the intestinal wall were detected; one involving the entire thickness, the other two the peritoneal coat only. At several points the omentum had been wounded, and the mesentery was cut in two places. The boy's woollen clothing had been torn by the teeth of the saw, and a great many minute shreds of the stuff deposited on the surface of the protruded mass. The three intestinal wounds were carefully sutured with very fine silk, after the method of Lembert. All the bleeding points were secured with fine carbolized catgut. Some ragged portions of omentum were similarly tied and cut off. Attention was next given to the cleansing of the peritoneal surface from all the bits of woollen threads deposited on it; a very tedious process, occupying more time than any other part of the operation.

In order to return the protruded mass it was necessary to enlarge the wound somewhat; after which reduction was accomplished without difficulty. After irrigation of the peritoneal cavity, the edges of the wound were brought together with silkworm-gut sutures, secured by shot. A glass drainage tube with a closed and rounded end was inserted, and the usual antiseptic dressings applied, with a flannel bandage over all. Every two hours the cotton rope filling the tube was removed, and suction was made with a hard-rubber syringe with a long nozzle, so as to prevent any accumulation of secretions.

Reaction took place very favorably; the boy had only very slight pain, but some nausea and vomiting, which continued all next day, subsiding toward evening. A free movement of the bowels occurred, and he learned later that an attendant, just after the boy's admission, had given him by mistake ten grains of blue mass, intended for another patient. As soon as the stomach became quiet, the administration of prepared milk and beef-tea, alternately every two hours, was begun. On the fourth day there was only a slight yellowish discharge from the tube. On the fifth day the glass tube was removed, and a soft-rubber one substituted for it. Solid food (milk toast) was given, and on the sixth day he ate an egg and some chicken-broth.

A day or two after this the tube was removed, and a few days later the sutures. For some two weeks after this the boy was kept in bed; he was allowed first to sit up in bed, and then to get up and walk about.

After the spontaneous movement of the bowels on the second day, an enema of turpentine and sweet oil was administered about every third day until his dismissal.

On October 31st, thirty-seven days after the injury, he walked into the clinic-room; and on November 12th he was discharged, with directions to wear a binder for some time, and to report before dispensing with it.

Certain features of this case may be briefly commented upon. The boy's youth was, of course, in his favor. He was stout and healthy, although his surroundings had not been, by any means, hygienic. But there was one circumstance of special advantage—the fact that the protruded mass quite filled up and plugged the wound in the abdominal wall. Besides this, the wounds were all of small extent, and no large vessels were divided. The presence of the almost innumerable shreds of soiled woollen clothing on the peritoneal surface was of course an element of danger, only to be set aside by the utmost care and patience in their detection and removal.

DR. JOSEPH PRICE said that the fact that the protruding intestine completely closed the wound had a great deal to do with the successful result in this case. We know that undue manipulation and prolonged and needless exposure of intestine are frequent causes of shock and death; this fact is beautifully illustrated in needlessly prolonged operations. He never could understand the vicious do-nothing policy of ambulance surgeons in these cases of abdominal incised wounds. The ambulance surgeon should be prepared and instructed to act promptly in such accidents. Promptitude is everything. A pitcher of warm water and a few threads might save lives that are lost by carrying the patient untreated, with the intestines exposed, covered by filthy clothing, to the distant hospital, there to wait for the chief to arrive before anything is done. He recently read of a case of a man who was accidentally eviscerated while hunting alone in the backwoods. Some one found him with the intestines protruding and covered with dirt, and carried him to the nearest brook, washed and sewed him up. He was also fortunate in *being away from opium* and from meddlesome nurses and officious residents of a general hospital, and he recovered. The strictest simplicity, absence of opium and of milk, indeed of all food till the patient asks for it, except in greatly exhausted cases demanding early support or stimulation, will give the happiest results. He gives plenty of fluids, toast water, barley water, stimulating enemata of beef-tea, with, perhaps, a little whiskey if needed, and enemata of water to relieve thirst. We

know how difficult it is to prevent hemorrhage in ether-nausea. Careful preparation for the operation by the free use of salines will minimize the ether and bowel disturbance. He is satisfied that the free use of the salines is of greater importance *before* operation than after in abdominal work. The unintentional administration of blue mass in this case of Dr. Packard's was a happy accident and helped recovery. He wished particularly to congratulate Dr. Packard upon the excellence of the toilet, the care to secure perfect cleanliness under such difficult conditions, and the perfect drainage. The careful removal of all foreign material from the bowel, free irrigation, and perfect glass drainage in two desperate cases have given him a triumph in two cases of abdominal work.

DR. PACKARD desired to say a word in reply to Dr. Price in defence of opium. If we remove a tumor all goes well until water is injected into the abdomen. Pain ensues immediately. We give a grain of the extract of opium by the rectum, when the pain disappears the patient goes to sleep and wakes in comfort. Are we not justified in attributing this to the opium, and relying on the same measure in similar cases? Of course, it would be a great mistake to treat all cases of peritonitis with opium. The saline treatment is proper in suitable cases, and saves many lives. So may we say of opium in suitable cases. The error is in exclusiveness, whether in the one direction or the other. We must use our judgment in individual cases, and prescribe in view of all the conditions present. In this case he thought nothing would have served his patient as the one grain of the extract of opium did. It was not a case of peritonitis however, and he did not so regard it. But suppose some enthusiast in salines had ticketed the case peritonitis and immediately administered purges, he hardly thought such prompt relief would have been afforded. He would like, while on this subject, to mention a measure which he had employed for many years, and which has repeatedly seemed to him to avert threatened peritonitis, and that is the application of a dozen leeches to the abdomen. After operation for stone especially, as well as in other cases of traumatism, marked benefit has been derived from the adoption of this plan.

NEWS ITEMS.

The German Imperial Health Office.—The Government proposes a change in this office for the coming year, rendered necessary by the increased amount of statistical work required of it. The proposed change is in the direction of the institution of a new department for the carrying on of this work. All other departments will remain as before, with the exception of the changes in the mere *personnel* of the staff, and are estimated to cost for the year, in round numbers, about 135,000 marks.

Only one of the original ordinary members of the office, which was founded thirteen years ago, still remains at his post, viz., Prof. Sell, the director of the department relating to the chemical investigation of foods. All the other posts have undergone changes as to their incumbents. After several changes, the post of hygiene was occupied by Dr. Renk. When Prof. Robert Koch took over the chair of hygiene at the University, he still retained a seat on the board in the allied department of epidemiology and bacteriology, and as ordinary member for hygiene came his pupil, Dr. Gaffky, who has since been translated to Giessen as professor of that branch of science. His post in the health office is not yet filled up, but the duties are temporarily performed by Dr. Petri, the former assistant of Koch, and curator of the hygienic museum. It is expected that he will be promoted definitely to the post he now fills provisionally, and that his place in the musenm will be filled by the appointment of Dr. Erwin von Esmarch, a son of the celebrated Kiel professor of surgery.—*Medical Press*, December 19, 1888.

Proposed Inoculation for Yellow Fever.—A press telegram states that DR. PAUL GIBIER, of Paris, who some years ago, in Spain, inoculated himself and others with the germs of cholera then raging there, the inoculation proving successful, will offer his services to the United States Government to establish an experimental station for treating yellow fever.

Dr. Gibier, in discussing his plans, is reported to have said: "I think a safe method of inoculation and care of human beings will result in the prevention of yellow fever. If the Governmnut desires it, I shall offer my services to establish a laboratory on one of the keys off the Florida coast, and, getting fresh matter from Havana or Key West, stock my island with monkeys, and spend a year, if necessary, perfecting a method of treatment of the fever. I shall report what I have done so far to the medical societies here and in Washington."

The Memorial to the British Medical Association.—*The Medical Press*, December 19, 1888, states that it understands that a private meeting of the signatories to the memorial recently presented to the President and Council of the British Medical Association took place recently, to consider the reply of the Council thereto. A large number of influential members were present, and although being a private meeting, it is not at liberty to divulge the details of the proceedings, it may be stated that it was generally felt that the *Journal* was not conducted in such a manner as to raise the moral tone of the profession, but, on the contrary, it was subverted to favor the interests of those whose line of action does not accord with the views of right-thinking men. It was urged that the Association expended a large sum of money annually on the *Journal*, and was under an obligation to exercise a strict surveillance on its management. It would seem that the dissentients are not disposed to rest satisfied with their abortive protest, and the futher evolution of the movement is awaited with interest and curiosity.

The Mortality on the Panama Isthmus.—The tribute of valuable lives paid to the insalubrity of the Panama isthmus (says *Engineering*) has been very heavy. M. A. Nichols, who had the organization of the sanitary measures for the protection of the workmen, states that amongst the European element there have been 5200 deaths during a period of two years and three months, the burials averaging about seven per day, and the death-rate being 98 per 1000 In one station, amongst 159 young men specially selected for their physical vigor, 23 have died within twenty-two months. Amongst the colored workmen the loss has not been anything like so

heavy, only 51 having died out of 2100 during the period considered.—*Lancet*, December 22, 1888.

Disinfection of Surgeons' Hands.—A great deal has recently been said about surgeons' nails and nail-brushes in hospital wards. Bacteriologists have come to the conclusion that the usual washing of the hands with weak antiseptics is quite efficacious in killing pyogenic and specific germs on the hands, but does not destroy micro-organisms which lodge under the nails. Dr. Fürbringer, of Berlin, believes in washing the hands with soap, then with alcohol at 80° F., then in a sublimate solution. The alcohol is said to soak well into the nails. Drs. Roux and Reynès have tried experiments with alcohol on nails purposely infected. In forty cases in which the infection was experimental, and carried on in the laboratory, asepsis was proved in thirty-three. In eight cases in which infection was clinical, the hands being washed in the usual manner after touching infected fluids, only four were proved aseptic after the above elaborate system of washing. Drs. Roux and Reynès nevertheless advocate this antiseptic ablution, noting that the nails are seldom so thoroughly rubbed after every operation as when an experienced physiologist cleans them after some special experiment. In all cases of enforced sanitary measures routine practices and habits must be taken into account. —*British Med. Journ.*, December 22, 1888.

Danger in the Postage Stamp.—The *Sanitary News* calls attention to the fact that a postage stamp may in various ways convey contagion. One of the simplest and most plausible, is that in which a postage stamp, partly attached to a letter to pay return postage, is sent by a person infected with some disease to another person. The disease is transferred in the first place to the adhesive stamp through the saliva, and in being attached to the letter by the receiver the poison may be transmitted to him in turn through the saliva. Another cause may be the infection of the stamp with disease germs. That this is true can be proven very simply by a microscopical examination.

We often see persons holding change for a moment in the mouth, probably not knowing that investigation has shown that disease germs can be carried by money. If they could see through what hands the money has passed, they would hesitate before using such a third hand. Silver money is as bad as paper money, but while many would hesitate to hold a dirty bank note in their mouth, they think that a silver piece, because bright, is apparently clean.

Photography of the Male Bladder.—According to the *British Medical Journal*, December 22, 1888, Mr. Hurry Fenwick and Mr. Pearson Cooper, of the London Camera Club, have been working for some considerable time at photography of the human bladder. Various obstacles were in turn recognized and overcome, and they have now so far perfected their vesical camera and method as to obtain good negatives of the interior of "dummy" and dead bladders. They hope before very long to describe a method of recording the appearances and progress of diseases of the living bladder. The negatives are taken *per urethram* through a tube of 23 French calibre (11 or 12 English).

Executions by Electricity.—It is reported that it is not unlikely that at the present session of the New York Legislature the law, which went into effect the first day of the year, providing for the execution of murderers by electricity, will be repealed, or the time extended for its going into effect. It is not altogether sure that executions by electricity can be made without pain or mutilation. Electricians are divided on the subject, and the majority seem to be opposed to the law. It is noticeable that every electrical journal opposes the electrical method of execution as inexpedient and inhuman, and in a recent address Professor Brockett, of Princeton College, spoke of execution by electricity as an outrageous thing and the degrading of a noble agent to an ignoble use.

But though the practicability of electricity as a substitute for hanging is thus thrown in doubt, the other provisions of the law passed last year ought to remain. The most important of them are the requirements that all executions shall be in private, at an hour only known to the Sheriff, and that there shall be no publication of the details of the event. There will probably be fewer murders when it becomes known that the criminal condemned to die shall be led to execution at an unknown hour and then put to death in the presence of only legal witnesses, and the fact of his execution made known to the world only by a brief paragraph in the papers. But electricians should be agreed as to the advantage of using electricity as the legal method of executing murderers, before the method is actually applied.

Counterfeiting Mellin's Food.—A druggist was arrested in Philadelphia last week, at the instance of the Dolibier-Goodale Company, charged with swindling and obtaining money under false pretences by selling as Mellin's food a spurious compound of his own manufacture under their name and registered trade mark. He confessed his guilt and in default of bail was committed to the County Prison. It is reported that this arrest will be followed by others, as the parties in interest are determined to follow up with rigor and prosecute all who are found to tamper with their labels and goods

Post-graduate Instruction in London.—The popularity and, it may be assumed, usefulness of post-graduate instruction has recently been proved to be beyond question in London, as well as in other large centres of medical learning. But so far, in the former case, only a limited field for the work has been available. One hospital only in the metropolis has been engaged in the organization of a post-graduate course, and it has probably been the success of this which has prompted the suggestion of the scheme which is now in process of elaboration. The scheme consists of seeking the cohesion of six hospitals with their staffs in London, with the object of laying open for post-graduate purposes the large number of seven hundred and sixty beds. The hospitals, in detail, are composed of one general, one for diseases of the eye, of the skin, of the nervous system, of women, and lastly, of children. The members of the staffs of these six institutions would be required to deliver lectures at some central situation, such as the Examination Hall upon the Embankment, at stated intervals, and give clinical instruction in the wards and out-patient rooms to the post-graduate students. We understand that the scheme has been submitted to the various hospitals here referred to, and meetings have

been held to discuss the matter.—*Medical Press*, December 12, 1888.

Sir Morell Mackenzie in Edinburgh.—Sir Morell Mackenzie in the early part of this month gave two lectures in Edinburgh, on the first day to the members of the Edinburgh Philosophical Institution in the Music Hall, on "Speech and Song," and on the second, to the students of Edinburgh University, in the U. P. Synod Hall, on "The Relation of Culture to Professional Success." Both lectures were well attended, and from the students Sir Morell had a most enthusiastic reception, and was presented by them with an illuminated address. Mr. J. R. Findley acted as chairman at the Music Hall, and Professor Campbell Frazer, Dean of the Faculty of Arts, at the students meeting. It is certainly a significant fact that Sir Morell was not accompanied to the platform on either occasion by any of the prominent medical men of Edinburgh. This might have passed without particular comment, had not the daily papers taken up the subject, and roundly abused the medical profession for their conduct toward the lecturer.—*Medical Press*, December 12, 1888.

The Limits of Professional Secrecy.—Professional secrecy has attained a degree of refinement and comprehensiveness in France which must seem strained to medical men who have before now found themselves obliged to reveal such details and information as an indiscreet counsel may take upon himself to require. Quite recently a very knotty question has suggested itself, and as it applies as much in this country as in France, it may be worth while to take cognizance of it. Is a medical man justified in remaining silent when his doing so may prove detrimental to a large number of persons?

The particular case which gave rise to the discussion was that of a lady living in one of the large houses let out in flats, who suddenly developed smallpox. It was ascertained that the porter, who had been ill for some time previously, was himself suffering from this disease. His condition had been purposely kept secret by the medical man in attendance on the ground that a breach of confidence would expose him to the penal clauses of the law which recognizes, and, if need be, enforces the reticence of medical men in respect of matters appertaining to their profession. From the French point of view, the doctor's duty would be limited to advising the patient to give the necessary warning, but in this country the medical man would probably be considered justified in taking the matter into his own hands rather than expose a whole category of persons to the risk of contagion.

As a general principle, the reticence of a medical man in all that concerns his relations with his patients is one which is in the highest degree commendable, but occasions may, and occasionally do, arise, in which the duty of the doctor to society at large must over-ride his duty to his patient. The notification of infectious diseases would probably fall within this category were it not that the object in view can better be attained by casting the responsibility of making the notification on the householder, merely obliging the medical attendant to give formal notice to his patient or patient's friends. The great point is that the plea of ignorance was not admitted as a valid excuse for non-notification.—*Medical Press*, December 12, 1888.

Bacteriology of Snow.—While the bacteriology of ice and hailstones has been studied with considerable success by Drs. Fränkel, Bischoff, Mitchell Prudden, Pumpley, Hills, Stoben, A. V. Poehl, Bordone-Ufreduzzi, Bujwid, etc., that of snow has been up to the present almost wholly neglected. Even in Russia the subject has been touched only in a cursory way by PROF. A. V. POEHL in a paper on "The Water-supply of St. Petersburg," in the *Vratch*, Nos. 8 and 9, 1884, p. 119. In it he points out: 1, that snow always contains viable microbes liquefying gelatine; 2, that, when snow falls, the first portions invariably contain greater numbers of bacteria than the subsequent ones (for example, 8324 per 1 cubic centimetre of snow-water against 3380 several hours later); 3, that, when snow lies on the ground, the superficial layers become richer in microbes (for example, 780 just after the fall, against 962 about three hours later). The fact is of interest from a sanitary point of view, as Dr. Poehl's researches furnish an additional proof that exposure of microbes to low temperatures does not destroy their vitality; at least, in certain species of microorganisms. In many countries, such as Russia or Sweden, snow forms, so to speak, a natural ground or soil during several months of the year, receiving excrementitious matter and every possible kind of refuse and filth. In spring, when the snow melts, it is imbibed by the soil, carrying with it all the polluting matters referred to. Hence an interesting question arises: Are such microbes as happen to be present in these matters in any way changed by their contact with snow, or not? This point can be determined only by further bacterioscopic researches.

A contribution to the subject has just been published in the *Vratch*, No. 37, 1888, p. 727, by DR. F. G. IANOVSKY, of Kiev, who has examined bacterioscopically, under Prof. K. G. Tritshel's guidance, a February snow in its purest state, collected both immediately and from one to three days after its fall. This observer has found: 1. That even when collected during its fall, snow is invariably found to contain living bacteria in considerable numbers, varying from 34 to 463 per one cubic centimetre of snow-water. 2. That their number does not decrease from exposure of snow to low temperatures (—16° C.) for several days. 3. That the following three species of microbes are met with constantly in great numbers: *a*, a large diplococcus composed of ovoid cocci, endowed with energetic motion, and characterized by its rapidly liquefying jelly; the test-tube culture on the third day, forming greenish colonies along the track of the needle, assumes the shape of a funnel-like sac with a whitish flocculent deposit, while on the fifth, the whole medium becomes liquefied, the precipitate sinking to the bottom; on agar a pale grayish-white streak is formed at the site of inoculation, on potato a fairly thick white film; *b*, small-sized cocci often arranged two and two, energetically mobile, and slowly growing on jelly without liquefying the medium, the growth proceeding solely along the track of the needle in the shape of a narrow stripe consisting of non-coalescing minute points of a yellow color, while on the surface the colony is seen as a grayish-white, circular, slightly prominent patch with somewhat fringed edges; on agar the coccus forms a white streak with sinuous edges, on potato a gray film with a brownish tint; *c*, very large cocci liquefying jelly as late as three weeks after inoculation, and growing

along the track of the needle in the form of a sharply defined streak of a beautiful pink color, with a slightly elevated pink circular patch or "cap" on the surface; on agar the microbe forms a freely spreading white film with a rosy tint, on potato a thick, tallow-like, pink coat with sharply defined fringed contours. 4. That the first two species (*a* and *b*) are also met with commonly in the water of the river Dnieper, which flows through the town (*vide* Dr. Ianovsky's bacterioscopic examination of the water, published in the *Meditzinskiĕ Obozreniĕ*, Nos. 9 and 10, 1888, p. 975), while the peculiar pink micrococcus seems to occur only in snow. 5. That, generally speaking, the microbes liquefying jelly in falling or recently fallen snow are met with invariably in far greater numbers than in snow which has been on the ground for some time; this, in fact, very often contains only such bacteria as do not liquefy gelatine. 6. That the bacteria of snow originate partly from aqueous vapors which are transformed into snow, partly and chiefly from the air; that is, they are carried away by the snow-flakes on their passage through the atmosphere. — *British Medical Journal*, December 15, 1888.

The Electric Light in Land Warfare.—The *Daily News* states that recently some interesting experiments were made on Hampstead Heath for the purpose of testing the capacity of small electric hand-lamps in searching for the wounded men left after a battle, and thus more rapidly than hitherto bringing the sufferers within reach of surgical aid. The experiments were made by the officers and men of the London Division of the Volunteer Medical Staff Corps, an organization which consists of four efficient companies, largely composed of medical students, and in which a fifth company is now in process of formation. The corps, under Surgeon-Commandant Norton, accompanied by ambulance wagons, and provided with stretchers, halted upon one of the Heath roads at a time when the thick mist hung heavily upon the lower grounds; and having established a dressing-station in a rather dreary-looking spot, poorly sheltered by bare trees, sent out its searching stretcher parties to pick up the bandsmen who had been distributed over the open ground at some distance off, to simulate the wounded left from a fight during the daylight. By the aid of the lamps thus brought into such a use for the first time, the men sought were found with comparative rapidity, and the stretcher detachment were guided back to the collecting station by electric lights at the wagons. The results achieved indicate sufficiently well that the electric light thus used would be of immense value, and tend greatly to reduce the suffering of men left upon the field at the close of a fight.—*Medical Press*, December 19, 1888.

The Influence of Parents' Age upon the Vitality of Children.—MR. JOSEF KÖRÖSI, Director of the Hungarian Statistical Bureau, read a paper upon this subject at the last meeting of the Hungarian Academy of Science, in which he gave the following observations, deduced from 24,000 cases:

Children of fathers under twenty-five are of a weak constitution; children of fathers whose age is between twenty-five and forty years are the strongest, while the offspring of fathers over forty are also weak. The offspring of a mother before her thirty-fifth year are the healthiest; those borne between her thirty-fifth and fortieth year are eight per cent., and those born after her fortieth year ten per cent. weaker. Children of old fathers and younger mothers are generally strong, while those of parents of equal age are somewhat weaker.—*Deutsche med. Wochenschrift*, Dec. 13, 1888.

Professor Roser.—The death is announced of Professor Roser, the eminent surgeon at the age of seventy-one, from the effects of an apoplectic seizure. The deceased had been for many years one of the leading members of the medical faculty at Marburg University, and was the author of several important works, among which may be mentioned *Handbuch der anatomischen Chirurgie* and *Eléments de Pathologie der chirurgicale spéciale et de Médecine opératoire* translated by Culmann and Sengel.—*Lancet*, December 22, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 1 TO JANUARY 7, 1889.

WATERS, WILLIAM E, *Major and Surgeon.*—Leave of absence granted in S. O. No. 129, November 9, 1888, Department of the Columbia, is extended one month.—Par 9, *S. O. No. 2, A. G. O.* January 3, 1889.

By direction of the Acting Secretary of War, FRED. C. AINSWORTH, *Captain and Assistant Surgeon*, will proceed to New York City, and Brooklyn, N. Y., on business connected with the Medical Department.—Par. 20, *S. O. 302, A. G. O, Washington*, December 29, 1888.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING DECEMBER 22, 1888.

HAMILTON, JOHN B, *Supervising Surgeon-General.*—Granted leave of absence for sixty days, December 20, 1888.

BAILHACHE, P. H., *Surgeon.*—To inspect unserviceable property at New York Marine Hospital, December 17, 1888.

WYMAN, WALTER, *Surgeon.*—To proceed to New York City and transfer public property, December 15, 1888.

CARTER, H. R, *Passed Assistant Surgeon.*—Granted leave of absence for fifteen days, December 10, 1888.

MAGRUDER, G. M., *Assistant Surgeon.*—Upon expiration of leave of absence, to proceed to New Orleans, La., for temporary duty, December 21, 1888.

COBB, J. O., *Assistant Surgeon.*—Leave of absence extended ten days, December 14, 1888. To proceed to Evansville, Ind., for temporary duty, December 20, 1888.

STONER, J. B., *Assistant Surgeon.*—When relieved, to proceed to New York City, for duty, December 13. 1888.

GEDDINGS, H. D, *Assistant Surgeon.*—Upon expiration of leave of absence, to proceed to New York City, for temporary duty, December 21, 1888.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL ARTICLES.

A STUDY OF THE CLIMATE OF COLORADO AS APPLIED TO THE ARREST AND CURE OF PULMONARY DISEASE.[1]

BY SAMUEL A. FISK, M.D.,

PRESIDENT OF THE COLORADO STATE MEDICAL SOCIETY, PROFESSOR IN THE UNIVERSITY OF DENVER.

IN the presentation of this subject I shall not attempt to argue the question of the advantages of a high altitude over those of a low, nor to extol the virtues of a cool climate as opposed to a warm, nor yet to praise dryness as contrasted with moisture. I shall accept the fact that the climate of Colorado is characterized by elevation and dryness, and it is essentially a cool climate, and on that basis will it be my endeavor to describe its several qualities, faithfully and impartially; to be eyes and ears for the reader, to be the observer in his stead, and, in so far as I am able, not only to state its good qualities, but its bad, so that I may be free from the charge, so often laid at our door, of being *ex-parte* in our writings, and of at least suppressing the truth even if we make no misstatements.

In selecting this subject for presentation, I am aware that I may lay myself open to the charge of offering nothing new; but so convinced am I of the merits of the Colorado climate, so many cures have I seen wrought in it, during my eight years of experience, and so efficacious do I believe it to be in the arrest or cure of pulmonary disease—in many of its forms—that I cannot refrain from adding my voice to those who are proclaiming its virtues, until, by sounding its praise so long and so loud, we may compel the world to hear.

"What do we mean by climate?" is the very pertinent question which Dr. Burney Yeo asks at the opening of his work on that subject; and he answers it by saying: "We generally mean by a question of this kind that we desire to know how the natural conditions and surroundings of a particular place affect the life and well-being of its human inhabitants." These conditions are the nature of its atmosphere, or aërial cloak, and the nature of its surface.

Let me speak of the latter condition first. The State of Colorado embraces a territory between seven meridians east and west, and four parallels north and south—that is, it is 380 miles long and 280 broad, having an area of 103,925 square miles, a superficies which is considerably more than double that of the State of New York, thirteen times that of Massachusetts, and twice that of England. The southern border of this tract corresponds in distance from the equator to Old Point Comfort, while its northern border equals Yonkers on the Hudson. Its most densely inhabited portion, however, corresponds very nearly to the space between Fredericksburg on the south and Philadelphia on the north, while its principal city (Denver) has the latitude of Baltimore in this country, or of Lisbon in the old world.

It is evident that in speaking of a climate of so vast a tract of country one can only mention the prevailing characteristics, and that considerable allowance must be made for deviations from that which is accepted as the standard. Through the centre of Colorado, running north and south, the Rocky Mountain range extends, its water-shed on the east emptying into the Mississippi River, by means of two small tributaries, the south branch of the South Platte in the north and the Arkansas in the south, streams which can easily be forded, and in summer time are so shallow, especially the Platte, that one can wade them without wetting the knee. The flow from the western water-shed is into the Pacific, through the Colorado River, while to the south a small portion of the State drains into the Gulf of Mexico by means of the Rio Grande.

I have spoken of these points because I wish to emphasize the fact that the drainage of the melting snow, from the 280, or over, miles of mountain-sides, whose waters flow to the east, is mostly subterranean, and that the surface is dry, affording a very slight amount of water. This factor is of most importance as contributing to the dryness of the climate, a condition which is due in a large measure to the distance which separates the State from any large body of water. Within the portion of Colorado lying to the east of the mountains, that portion most frequented by invalids, there are no large bodies of water from which the air can take up moisture, and a distance of over 900 miles from the Gulf, the nearest large body of water, is an additional cause for the exceeding dryness of the air of this State. Atmospheric dryness, due largely to geographical position, is one characteristic of the climate of Colorado. Of course, this condition is also affected by

[1] Read before the American Climatological Association, Washington, 1888.

atmospheric pressure, elevation, and temperature; but in the main it is due, as I have said, to geographical position.

But of almost equal importance, as has been ably shown by the researches of Bowditch and Buchanan, is the question of soil dryness. Here, again, the conditions are most favorable. To the east of the mountains, the portion of the State most inhabited, the land falls in a gradual descent from an elevation of about 6000 feet at the foot-hills, to one of about 3500 feet at the eastern border of the State, some 190 miles distant. Its surface is well drained into the two rivers I have mentioned, whose waters come principally from the mountain-sides, and, as a fact, most of these waters sink into the porous and thirsty soil to increase the subterranean flow, or to well up again as they near the mouth of the streams. Besides this natural drainage, favoring soil dryness, there are the additional features of a sandy and porous soil, which absorbs moisture rapidly, the absence of shade to retain it, and the further absence of precipitation to make it moist, as I shall have occasion to show further on in this paper.

Another property possessed by this climate due to the nature of its position is elevation. This varies from 3500 feet at the eastern border of the State, to 4500 feet at Pueblo, 5200 feet at Denver, 6000 feet at Colorado Springs, 7200 feet at Idaho Springs, 8000 feet at Georgetown, and 10,000 feet at Leadville. So that it is possible, within these limits, to give a patient any degree of elevation that may seem desirable.

Further than that, local configuration varies so that one can have his choice of open plain or of mountain valley. He can have the winter on dry ground at Colorado Springs, Denver, and numerous other places; or he can enjoy what Dr. Frankland and others place so much stress upon, in considering Davos Platz—that is, the solar radiation intensified by radiation from the snow in valley and on peak, such as occurs in narrow valleys amongst the mountains. The large area of the State admits of great variety of location, which can be taken advantage of by the invalid, and which our physicians are now studying and learning more closely. The common characteristics, due to surface and position, are: elevation, soil, and atmospheric dryness, rarefied air, an absence of shade, and a temperate clime, varied somewhat from the main characteristic by conditions induced by rarefaction of the air, absence of atmospheric moisture, and a sandy soil.

Let us turn now to a consideration of the atmospheric conditions prevalent in Colorado. Here, again, I shall give the prevalent and main characteristics, and I take the privilege of presenting those conditions that exist at Denver, for the reason that it is the centre of the State, as regards its population, and nearly so as regards its geographical position. It is the capital, the best known place in the State, and, further, meteorological records have been kept in it for the last dozen years.

The facts that I shall now proceed to give, I have taken largely from these records; I shall refrain, however, from giving tables, because they are wearisome, and must refer you to the writings on this subject

"The chief conditions of the atmosphere," says Yeo, "that affect the climate of a place, are these: (1) its temperature; (2) its movements (winds); (3) its amount of aqueous vapor; (4) its electrical conditions; (5) its purity; and (6) its density or pressure."

Dr. Frankland, in his article—"A Great American Winter Sanitarium for the American Continent," states as the qualities of climate existing at Davos Platz, which he regards so desirable: (1) great elevation above sea-level; (2) a continuous and, during winter, permanent snow-covering; (3) a minimum of watery vapor in the air; (4) a clear sun; (5) a clear atmosphere, free from zymotic germs, dust, and fog; (6) a sheltered position favorable for receiving both the direct and reflected solar rays. These views are sanctioned by Hermann Weber, Lindsay, Yeo, Tucker Wise, and others. Some places emphasize upon the presence of ozone; but as so little is known positively about ozone and about electrical conditions of the atmosphere, I think that we may dispense with any consideration of them, simply expressing the belief that whatever advantages come from their presence are common to Colorado with other high altitude resorts.

Taking, then, the gauge of the climate as set down by these eminent authorities, let me show to what extent they exist in Colorado, and how they are considered to be beneficial.

Elevation, or diminished atmospheric pressure, is presumed to induce a more rapid circulation, which may, in many cases, be beneficial by assisting the removal of the products of disease in the chest. On the other hand, in greatly enfeebled cases, it may so hasten metabolic change as to be highly injurious.

It also increases the number and depth of the respirations, a condition of affairs which is assumed by many to be due to the fact that the diminished oxygen in the rarefied air causes a so-called "starvation of oxygen," which requires a hastening of the respirations to supply the deficiency—a theory which Dr. Hermann Weber pooh-poohs, and which seems but little susceptible of mathematical demonstration. The increase in the number of pulse-beats and of the respirations, I think, tends to regulate itself after a residence in high altitudes. Authorities agree, however, that chest expansion does occur, and this may be beneficial as calling into play unused, or but feebly used, portions of the lung.

Beneke has shown that heat is lost from the self-same apparatus more slowly on the tops of moun-

tains than at the seashore, a fact which Frankland emphasizes with reference to the sensation of cold, when he says, "The air, if still, feels warmer at an elevated station than in the lower and denser regions of the atmosphere, in consequence of the slower abstraction of heat from the body."

Hermann Weber speaks of the fact, that at elevated regions blood flows to the surface of the skin, that it thus becomes better nourished, that internal organs become unloaded, and that the elimination of carbonic acid from the blood of the lungs is facilitated.

Whatever benefits come to the human economy from a residence at high altitude, and I have mentioned some that are presumed to accrue, they are to be gained by living in Colorado, where the elevation of the inhabited portion of the State ranges from 3500 to 10,000 feet.

Humidity.—This element is highly variable in mountain resorts; it depends on the character and direction of the prevailing wind, and on the local configuration; the tendency, however, is toward dryness rather than humidity. I have already shown how the geographical position and configuration of the surface of Colorado tend to the production of atmospheric dryness; of course, the rarefaction of the air aids in the same direction. But now let me state the facts:

The average mean relative humidity for a series of years I have calculated to be only 45.8 per cent. of saturation, as against 69 per cent. in Jacksonville, Florida; 70.2 per cent. in New York; and 65.8 per cent. in Los Angeles, California. I have also shown, in a previous writing, that this mean is reduced to an average mean of 41.5 per cent. at noonday for the eight winter months of September to April inclusive, and that it not infrequently sinks to 25 per cent. of saturation; a condition that in Switzerland would endanger the production of the Föhn.[1] If, instead of relative humidity we speak of absolute humidity—*i. e.*, the number of grains of vapor contained in a cubic foot of air—the showing is immensely in favor of Colorado, inasmuch as rare air at a given temperature will hold less moisture than a denser air at the same temperature. The mean absolute humidity for Denver for a series of years was only 1.81 grains of vapor, as against 5.38 grains at Jacksonville; 3.02 at New York; and 3.77 at Los Angeles.

All authors attest the value of dry air in the arrest or care of pulmonary disease, and the influence of moisture in its production. A patient in search of a dry air cannot do better anywhere in the United States than to come to Colorado.

Sunshine.—It is in this particular that the Colorado climate is particularly strong. Figures show that, according to the signal service method of reckoning cloudy days, there are only 46 such in a year in Denver, as against 87 in Jacksonville; 109 in New York; and 51 in Los Angeles. This, however, takes into consideration the whole twenty-four hours. If we approach the subject in another way, with reference to the ability of a patient to be out-of-doors during the daytime, we may take as a gauge what occurred in the winter of 1884–85, considering the months of September to April inclusive, in which time I find that there were only eleven days, out of two hundred and forty-two, which were cloudy all day long—that is, when the sun did not shine at all from 9 A.M. to 5 P M.

Certainly a counting of three hundred and twenty days of clear or fair weather in a year, when the whole twenty-four hours is considered; or of two hundred and thirty-one days out of two hundred and forty-two days, taking the hours from 9 A.M. to 5 P.M., is a tremendous showing of the extent of sunshine that occurs in Colorado,

But this is not all. The principal resorts lying, as they do, on the edge of the plains, and not being sheltered by mountains, enjoy a number of hours of sunshine a day such as few mountain resorts can boast. A comparison will make this clearer. Dr. Tucker Wise has stated that on the first day of January the number of hours between sunrise and sunset in the Alpine resorts are as follows:

	Hours.	Minutes.
Maloja	7	10
Wiesen	6	10
Pontresina	6	40
St. Moritz	5	5
Davos Platz	4	57
Andermatt	3	30

By way of comparison I introduce Denver, nine hours and seven minutes, or nearly twice that of the world-renowned Davos.

Not only does Denver enjoy so many hours of sunshine, but there is the additional consideration that the sun is up, warming the air, a number of hours before the invalid gets out-of-doors, while at Davos and other Alpine resorts the sun and the invalid make their appearance together. The following figures of sunrise will show this; Maloja, 9.25 A.M.; Wiesen, 10.35; Pontresina, 8.30; St. Moritz, 10; Davos Platz, 10.03; Andermatt, 11.45; Denver, 7.30, for the first day of January.

Knowing the warming influence of solar radiation, the part that these early hours of sunshine play in making the air comfortable for the invalid cannot be overestimated. It is like having a fire built in a cold room an hour or two before a patient arises, or having it lighted just as he tumbles out of bed.

One more influence of sunshine, and I will then proceed to other topics. The mental influence, the cheer which bright sunshine, clear, warm air, and a dry soil give to a life out-of-doors, thereby *inviting*

[1] A humid south wind on the Swiss lakes.

and not forcing the invalid to a drive, a walk, a ride, a game of tennis, and to all healthful out-of-door influences. I cannot lay too much stress upon this factor of Colorado sunshine—an important, if not the most important, feature of our climate. I would like to touch on it from the more poetic side, telling of the color it gives to daily life, but I must hasten to other considerations.

Temperature.—The question of the temperature of the Colorado climate is one of the most difficult to treat, because it involves a consideration of the difference between day and night, between the sun and the shade, between mountain and plain, between month and month. Broadly speaking, the days of the summer months are uncomfortably hot, in the cities, but even then the nights are cool, generally requiring that one be covered with a blanket, so as to be comfortable.

There is no denying the fact that Denver and even Colorado Springs were intolerably hot this past summer. Even admitting this, the advocates of this climate can respond that the invalid should go to the mountains, where in Extes Park, Manitou Park, Georgetown, Poncha Springs, Twin Lakes, and other places, he can breathe the purest air and have comfort. But the main consideration is one of the winter months, say from September to April inclusive. Here, again, I must admit many of the adverse criticisms made in regard to our climate. One writer, hunting the records over, for years, accuses us of having a diurnal change of eighty degrees in twenty-four hours, and he was correct, such a variance does occur—occasionally.

The meteorological conditions producing this change involve so well known a principle that it scarcely seems worth while to discuss them. Land radiates heat more rapidly than water, it becomes heated and loses its heat much sooner than water; and a dry, sandy soil will do this more rapidly than a moist. Shade and vegetation hinder both processes, so that the absence of shade favors both the heating and the cooling process. A rare, dry air favors the transmission of solar heat, by robbing it of but little of its intensity, and it also aids and abets terrestrial radiation.

These, then, are the conditions existing in Colorado: a dry, sandy soil; a lack of shade and vegetation; a rare, dry air. The result is a rapid warming up under the influence of the sun; a rapid cooling when that influence is removed. Hence we do have warm temperatures by day, and cool temperatures by night, and the difference does, at rare times, amount to eighty degrees. But, for the purposes of an invalid, the warmth and not the cold should be considered, because the latter comes at night when the invalid should be housed and can regulate the temperature, while the former is at mid-day when he is getting his exercise out-of-doors. A temperature of 62° at noon is of more importance to him than one of minus 18° at midnight. But Colorado climate is, in winter, a cool climate. The monthly mean for

January, 1886, at 1 P.M. was	27.3°
February, " " " "	48.0°
March, " " " "	41.1°
April, " " " "	52.3°
May, " " " "	74.3°
June, " " " "	75.1°
July, " " " "	85.2°
August, " " " "	81.5°
September, " " " "	72.0°
October, " " " "	64.2°
November, " " " "	41.3°
December, " " " "	45.5°

This is the temperature of the air at the time of day when an invalid is most likely to be out of doors. If these means seem too cold to the student of climate, I can only urge in extenuation: (1) To quote from Dr. Hermann Weber: "It is only a remnant of our old prejudice which can make us afraid of dry, calm, moderate cold;" or (2) as pointed out by Dr. Frankland, and as every person who has had experience knows, that "the air, if still, feels warmer at an elevated station than in the lower and denser regions of the atmosphere;" and (3) that the solar radiation must be taken into consideration, which transforms, to one in the sunshine, the air temperature from one of 27.3° F. at noon in January, to 92.5°; or the air temperature of 45.5°, in December, to the heat in the sun's rays of 100.2°.

No one, I think, need be apprehensive of cold days in Colorado, unless he be so much impoverished in physical condition as to make him an unfit subject for our climate. In most cases the inhalation of dry, cold air stimulates the respiratory functions to greater activity, leading, as Dr. Weber asserts, to greater expansion of the lungs and thorax, to improvement of the appetite and nutrition, thus exercising a beneficial influence on the course of phthisis.

Winds.—Statistics show that the average daily movement of the air in Denver is 145 miles as against 238 miles in Boston, 207 in New York, and 159 in Jacksonville; the data further prove that at 9 A.M. the average hourly velocity is 6.7 miles during the eight months, September to April inclusive, 8 miles at 1 P.M., and 8.6 miles at 5 P.M. Despite this low average, we are constantly accused of having high winds, and of the dust and sand storms being so disagreeable as to be detrimental to an invalid. With a view of meeting this criticism I collected data, awhile ago, which showed that in the year 1886 there were only twenty-three days in which there occurred a wind of eighteen miles or over, at two consecutive observations of the three 9 A.M. and 1 and 5 P.M., and that there were about an equal number of times when there was a wind of equal

velocity at only one of these three observations. Now, a wind of eighteen miles velocity is not a high wind. It is less than double the average velocity of the air in Boston, and is not more than a stiff breeze.

We do have occasional high winds, and they occur more frequently in some places than in others, but we are not entitled to the reproach so frequently hurled at us, that the winds and dust storms spoil the climate. The truth is, that owing to the sandy character of the soil and the absence of snow covering, a wind of moderate velocity will lick up the dust and set it a flying, while a stronger wind, as of eighteen miles per hour, will set up what is called a dust storm. These are no more disagreeable than I have witnessed on Commonwealth Avenue, in Boston, many and many a time. From the nature of things they are more frequent in the narrow streets of Denver than in the open country, or in the health resorts, and are in no way to be ranked with the cyclones of Kansas, or even with the gentle and moderate breezes of the peaceful Connecticut Valley, which I have known to blow over bridges and tear up hundreds of elm trees by the roots.

These dust storms are disagreeable, principally so in Denver, where the streets are the natural soil, which becomes dried by the ardent rays of the sun and pulverized by travel, so that they have to be constantly watered, even in January and February. But the frequency and violence of these storms have been very much overstated, and they do not seriously impair the invalid's comfort, or keep him indoors much of the time.

Precipitation.—The average yearly fall of rain and snow (melted) is 14.77 inches as against 55.94 in Jacksonville; 49.47 in Boston; 42.7 in New York; and 18.97 in Los Angeles, and of these 14.77 inches the greater part falls in the spring and summer months. Snow does not lie upon the ground in winter, and when it falls it is rapidly licked up by the dry breezes or drunk up by the porous soil.

Drs. Frankland and Weber consider a snow covering in winter of advantage because it keeps down germs, and also because, by reflecting the sun's rays, it increases the solar radiation. The former reason may be a valid one, but is it not counterbalanced by the deleterious effects of the thaw and by the decomposition and decay that are then induced? Is it not also more than counterbalanced by the disadvantage that a heavy covering of snow and ice is to the invalid who wants to drive, ride, play tennis, walk, climb, and lead an out-of-door life from nine o'clock in the morning until five o'clock at night? We in Colorado think so, and we prefer free and untrammelled locomotion on dry soil, even though there may be a few germs afloat, to wet feet, cold, hampered exercise, thaw, and everything that must follow up the existence of a deep snow covering.

As regards solar radiation, I have previously shown that while the mean average in the Maloja for November, December, January, and February was 103.75°, that in Denver it was 99.75° for the same time, a difference of four degrees in favor of snow covering, but not of material difference when one considers the actual temperature. If an invalid is not comfortably warm in a sun temperature of 99.75°, it is to be doubted very much whether 103.75° will warm his thinned blood.

Fogs.—Almost unknown. In the winter of 1884-1885 there is not a record of a single fog from the 1st of September to the 1st of May.

Purity of the Air.—I have left a consideration of this factor to the very end, because I wish to bring out certain points in connection with it. Generally speaking, every one acknowledges the purity of mountain and of sea air. We are in the habit of saying that it contains more ozone—a factor of which we do not know much. Basing our ideas upon the investigations of Pasteur, Tyndall, and Miquel, we say it is aseptic, free from germs, and we place the limit of germ-life at elevations ranging from 5000 to 7000 feet. I wish to raise the question whether we are right in so doing, and whether this principle may not be varied by other influences, so that instead of being taught to believe that altitude, in itself, is a germicide, we shall not rather believe with Hermann Weber, "That wherever a large number of human beings, especially invalids, congregate, there the purity of the air is likely to be impaired."

That there is germ-life in the air of Denver and of towns in Colorado I am assured. Urine decomposes nearly as readily in these places as in Boston, and if one wishes to be sure that the casts are not eaten up by little vibrioles, he must make his microscopic investigation early, just as he would in the East. Moreover, I have seen dead cattle lying on dry ground in Colorado, at varying elevations, subject to the drying effect of the sun's rays, which would desiccate, shrink up, and fall to pieces; and I have seen other dead cattle, at equal elevations, lying where there was some moisture, from which a most noisome stench would emanate. Certainly we do have decomposition at all elevations in Colorado, and that means putrefaction and, consequently, germ-life.

Where there is an absence of putrefaction in our climate, it seems to be due to the dryness of the air rather than the absence of germ-life. But even admitting the presence of germs, it does not militate against the purity of the Colorado air, for whatever qualities belong to mountain air certainly can be found in the air of our Rocky Mountains, whose sides are studded with towns up to an elevation of 11,000 feet, and whose summits tower into the skies at 14,000 feet,

It has often been said that different animals seem

to possess different degrees of sensitiveness to the rare air of mountainous regions, and that the cat cannot exist at great elevations. This assertion, with others, should be subject to modification, for I know of one cat that lived for ten years at an elevation of 11,000 feet, and in Leadville, 10,000 feet, they are not at all absent.

Résumé.—These, then, are the general characteristics of the Colorado climate: (1) elevation; (2) dry air; (3) a large amount of sunshine; (4) a warm sun temperature; (5) a somewhat variable temperature, cool, not cold, in winter—cold during a winter's night but comfortable at mid-day; (6) a moderate motion of the air, with occasional high winds; (7) a small snow- and rain-fall; (8) the absence of fogs; (9) a pure air; (10) a dry, sandy, well-drained soil.

But the simple narration of these climatic conditions in no way rounds out a just description of the arrest of consumption as applied in the Colorado climate. It does not tell of the local conditions of the different resorts; of the out-of-door life; of the diet and exercise; of the home life; of ranch life; in fact, of the various local conditions and of the means adopted to aid recovery, many of them varying from those employed elsewhere.

A description of this side of the subject furnishes too large a field to be handled by me at the present time, and in their individual application to the various cases of consumption they should be left entirely in the hands of a competent physician residing in that climate. One feature cannot be too strongly emphasized as characteristic of the Colorado cure. It is an all-year-round resort and not simply a winter resort, and, further, our State is an active, growing community, and there is plenty of room for the energies of the most active, when once a recovery is secured, so that a return to old methods and haunts is not to be recommended.

The State now claims a population of over 350,000 inhabitants. How many of these have come for reasons of health it would be difficult to say. Every town and every city has its large percentage of such people, who, in their persons and in the energy of their lives, are the strongest testimony that can be given to the efficacy of the Colorado climate in the arrest and cure of pulmonary disease.

HYPERPLASIA OF THE LYMPHATIC TISSUE OF THE PHARYNX AND NASO-PHARYNX.[1]

BY J. W. GLEITSMANN, M.D.,
PROFESSOR OF LARYNGOLOGY AND RHINOLOGY IN THE NEW YORK POLYCLINIC.

THE important group of diseases embraced in the title of this paper are of the utmost interest to the general practitioner, and, although they have been known for some time, experience has taught me that they are often overlooked, or mistaken for other affections.

Before entering upon the pathology and the clinical features, I desire to offer a few remarks upon the anatomy of our subject. The lymphatic tissue in question is embedded in the mucous membrane of the pharynx and naso-pharynx, either as a uniform, well-defined infiltration, or as so-called follicles, also named adenoid tissue by Hiss, and it appears under three forms. We have a simple, diffuse infiltration of the connective tissue with lymph-cells, further denser foci extending over a larger area—for instance, Peyer's glands of the intestines; and, finally, a circumscribed form, which is known under the name of tonsil. The lymphatic tissue appears in the locality which interests us in this paper, in an aggregated as well as disseminated form, and is distributed uninterruptedly throughout the pharynx and naso-pharynx. Waldeyer gave it very appropriately the name of lymphatic ring of the pharynx. Its position is almost vertical, and beginning at the naso-pharynx with the pharyngeal or Luschka's tonsil, it extends to the orifice of the Eustachian tube, where we have a larger aggregation of follicles, the tubal tonsil. Turning downward along the posterior edge of the soft palate, and around the posterior pillar, it reaches the faucial tonsil, and returns across the base of the tongue in a similar manner, to the naso-pharynx.

The abnormal conditions which we have to consider occur almost exclusively in localities where the tissue appears in the aggregated form, the tonsils, and its diseases, as a rule, have either an inflammatory or hyperplastic character. It is only the latter we will treat of to-day, and as the process, occurring in different parts of the pharynx, presents different symptoms and requires different treatment, each affection has to be considered separately. In order not to extend my paper unduly, I have selected the three regions where hypertrophy is most frequently observed, viz., the naso-pharynx, with the pharyngeal tonsil; the pharynx, with the faucial tonsils; and the lymphatic tissue at the base of the tongue, also called lingual tonsil. I shall only dwell at some length on the pharyngeal and lingual tonsils, and but briefly consider the hypertrophy of the faucial tonsil, so familiar to all practitioners.

Hypertrophy of the pharyngeal tonsil, as well as adenoid vegetations of the naso-pharynx, which latter name is given to these growths in children by their discoverer, William Meyer, of Copenhagen, are far more frequent than is generally assumed. It has been my good fortune to meet with an unusually large number of such cases since my return to the city, in September, and I preserved the specimens removed within the last three months, which I beg to hand you herewith. Quite a number of cases were brought to my office, in which treatment had

[1] Read before the New York County Medical Association, December 17, 1888.

been instituted for hypertrophic tonsils, or nasal catarrh; of course, without the desired result.

Regarding the age of patients, cases have been reported in which symptoms of the disease had been noticed from birth; but the children coming under observation are generally two years and older, the largest number being between five and fifteen years of age. With increasing age, the liability to the disease decreases proportionately. Sex does not seem to exert a special influence, the number of male and female patients being about equal.

In the majority of cases we observe one or more of the following symptoms: catarrh, alteration of the voice, impediment of respiration, affections of the ear. Although there are cases without catarrhal symptoms, most patients have more or less secretion of mucus either in the nose or the pharynx, and, in some instances, this is the chief reason for seeking medical advice. When hypersecretion was present, I found it oftener in the nasal cavities in children, whilst adults complained more of an abnormal sensation of mucus in the pharynx. But there are undoubtedly a considerable number of patients whose nostrils are perfectly free from discharge, and present no anomaly whatsoever.

Alteration of voice, and still more the changed character of the respiration, are the symptoms most apt to attract the attention of the parents to the fact that their child is unwell, and requires treatment. The voice has lost its resonance, is muffled, is called "dead voice" by William Meyer. Children as well as grown people speak with a nasal twang, and the nasal sounds are imperfectly pronounced. Instead of *m* and *b* they will say *n* and *d*. The voice is similar to that observed in paralysis of the soft palate, the functions of which are often interfered with when the vegetations are very abundant.

The impediment in respiration is generally the first symptom observed by the relatives of the patient, and, at the same time, the most important one. It does not require a very large development of these growths, especially in the small naso-pharynx of children, to make nasal respiration difficult or altogether impossible, and the patient becomes a mouth-breather. I shall not here dwell in detail on the function of the nose as an organ of respiration—for instance, for warming, moistening, purifying the air—I shall only speak about the more important features noticeable in our little patients.

To begin with the nursing infant. When the child takes its mother's breast, it has its mouth closed and breathes through the nose. If this is impossible, nursing is frequently interrupted to allow breathing, the child becomes fretful, and not receiving sufficient nourishment, his physical development seriously suffers. Furthermore, children with adenoid vegetations have restless, agitated sleep, they snore, the respiration is labored, stops occasionally altogether for a short time, the child becomes partly awake, only to begin the same turn over again as soon as asleep. These symptoms are so distressing that instances have been reported in which, after successful removal of the vegetations, parents were for several nights in a state of anxiety, owing to the absence of the familiar and accustomed noise and snoring.

This mode of respiration in time also exerts deleterious influence on the configuration of the chest and face. The chest-walls remain flat, are consolidated in the lower portion, corresponding to the insertion of the diaphragm, which attempts to overcome the impediment of respiration by energetic contractions. This condition, known and described for some time past as due to hypertrophy of the faucial tonsils, is just as often brought on by adenoid vegetations. The imperfect aëration and decarbonization of the blood make the child pale and anæmic. Such children are languid, their mental development is often retarded, they are bad scholars and slow in perception. Mouth-breathing of many years changes the aspect of the face. The open mouth, the protruding teeth of the upper maxilla, the disappearance of the naso-labial folds give the face a stupid expression.

A large number of our patients suffer from affections of the ear—according to Hartman, seventy-four per cent.—and all degrees of aural disease, from slight deficiency of hearing to purulent otitis, come under observation. Sometimes the aural trouble is only functional, without pathological changes, and is then caused by the pressure of the vegetations against the Eustachian tube, and consequent closing of the latter. I have treated several cases of hard breathing, in which the ear was sound and the treatment exclusively confined to the disease of the naso-pharynx, with the desired result.

According to Schaefer, 19 out of 100 cases of adenoid vegetations are complicated with hypertrophy of the faucial tonsils, and it thus happens that the symptoms are often attributed to the latter, and the disease of the naso-pharynx is overlooked. A limited number of patients complain of supra-orbital neuralgia. Headache, asthma, and also enuresis have been reported cured after removal of the vegetations.

The diagnosis is not so difficult as it would seem at the first glance, although a satisfactory rhinoscopical examination is out of the question in very young children. The best, easiest, and quickest way to ascertain the condition of the naso-pharynx is the introduction of the finger behind the soft palate. Whoever has touched these soft, velvety, mushroom-like growths, will always recognize them again. Although a mistake is scarcely possible, it is advisable to familiarize one's self with the sensation the finger experiences when introduced into a normal pharynx, in order to accomplish the examination in a safe and quick manner.

The treatment is highly satisfactory, as after destruction of the vegetations they are not apt to grow again. Topical treatment with iodine solutions, caustics, etc., having proven too tedious and ineffective, surgical proceedings have been generally adopted. Some surgeons operate by pushing ring-knives through the nose into the naso-pharynx, but the majority prefer to operate by introducing either curettes, sharp spoons, or the post-nasal forceps through the mouth. The latter instrument has been subjected to many modifications, and is now in general use. It is best to remove as much of the growth as possible at one sitting, and to assure ourselves by rhinoscopic or digital examination of the result of the operation. There is no objection to the use of ether in the operation, and, in fact, some operators always employ it. I generally succeed without ether, and only in rare instances have been obliged to introduce the forceps more than twice, or, at the most, three times. Too harsh and rough operating may be followed by fever and general malaise, also purulent otitis; but I, myself, have never experienced an untoward after-effect, except once, an accident which, to my knowledge, has not been reported by others. The patient, a lady eighteen years old, had a broad-seated hypertrophy, the larger portion of which was removed at the first sitting. A second operation was performed four days later to remove the remaining basis, and was accomplished without great difficulty. After her arrival home she was seized with a most violent hemorrhage, which recurring again the next day, necessitated the plugging of the naso-pharynx. The patient made a complete recovery.

After operation the patients should remain at home for a day or two, and when there is free discharge from the wound-surface, detergent and disinfectant solutions can be sprayed or injected into the naso-pharynx and nose.

The second part of our subject, the hypertrophy of the faucial tonsils, is so well known that I shall confine my remarks to two points only, viz., hemorrhage after tonsillotomy, and the use of the galvano-cautery.

Excision of the tonsil is always followed by a slight loss of blood, sometimes by a serious, even dangerous hemorrhage. In a very large number of tonsillotomies in my practice, all of which were performed with Tiemann's tonsillotome, three copious hemorrhages occurred. In the first two cases I was present when the bleeding took place; the third patient was already far away from my office when the bleeding began, and he had to call in the services of another physician. The history of the three cases is briefly as follows:

Case I.—A strong, healthy woman called in the afternoon at the German Dispensary and complained of throat trouble, which, on inspection, was found due to a hypertrophic tonsil. Except a slight hyperæmic condition of the fauces, nothing abnormal could be seen, and the excision was easily performed, followed by the usual slight bleeding. Toward evening I was called in great haste by her husband, who informed me that his wife had been bleeding ever since her arrival home from the dispensary. When I reached the patient, I attempted first to remove the coagulated blood, in order to find the bleeding vessel, if possible. During the procedure the woman fainted, and whilst being carried to a lounge, began to throw up blood in quantities I had only seen in pulmonary hemorrhage. Not to lose any more precious time, I inserted my index finger into the pharynx, and by using and continuing for ten minutes pressure against the tonsil and counter-pressure from the outside, effectually arrested the hemorrhage.

The second case was similar to the previous one, except that the bleeding began immediately after excision of the tonsil.

Case II.—The patient, a lady of about twenty years of age, was operated upon at the New York Polyclinic, by one of my assistants, in my presence, and the means employed to stop the hemorrhage were the same as in the preceding case.

Case III.—The third patient was a physician, on whom I operated in my office, and who left me after the first slight loss of blood had stopped, without any untoward symptom. When I saw him again, a week later, he related to me the following: On his way home he began to spit blood, and thereupon entered a drug-store, for the purpose of applying hæmostatics. Unable to control the bleeding, he went to the office of a medical friend, who, after several prolonged and fruitless efforts to stop the hemorrhage, finally took him to one of our hospitals, where it ceased after the patient was put to bed. It took him several days to overcome the ill-effect he had sustained from the loss of blood.

If I were asked, Have we positive signs by which we can determine if a tonsillotomy is likely to be followed by a hemorrhage, or not? I must say, we have not. But I have profited by my experience, and, although not slow in employing the knife, and preferring tonsillotomy to all other destructive means, I have, in two instances, flatly refused to operate. The two patients had hyperæmic, angry, red-looking tonsils, much more so than the first patient, whose history I have just related. The tonsils were not in an acute state of inflammation, but there was decidedly chronic enlargement. In both instances I dreaded hemorrhage so much that I did not practise excision. In other cases we may receive the warning of a possible hemorrhage during the operation. When the instrument cuts through the tissue with difficulty, finds much resistance, or when we hear or feel a grating sound, we may be prepared for a subsequent hemorrhage. The connective tissue, in such cases, is either so prolific and dense, or interspersed with minute calcareous deposits, that the cut

bloodvessels cannot retract and collapse, but are kept open by the unyielding, hard tissue. I may add, that I never saw alarming hemorrhage follow tonsillotomy in children.

The employment of the galvano-cautery as a means of reducing enlarged tonsils has, of late years, gained much favor amongst the profession. Quite a number of surgeons prefer it to the cutting operation, on account of dread of hemorrhage, but in a certain class of cases it is, so to say, the only means to the desired result, leaving out of consideration caustics, like chromic acid, Vienna or London paste, etc. In inflammatory processes of the tonsils the diseased organ often forms adhesions with the anterior pillar of the fauces, which then covers the tonsil, either hiding it entirely from view, or letting only so small a part protrude beyond it that it is impossible to grasp it with any cutting instrument without injuring the pillar. Here the use of the galvano-cautery is in place, and very few sittings (from five to ten) are sufficient to bring on the necessary reduction in tonsils of large size. The platinum point is immersed either into a crypt, or into the mass of the tonsil itself, and several days have to elapse before the reaction has subsided, the slough comes off, and a second application can be made. The instruments required are either a fine cautery-knife, or a pointed platinum electrode, and any good cautery battery.

The third and last subject of my paper, the hypertrophy of the lingual tonsil, has only of late years been more fully investigated. As I read an essay on this subject a year ago,[1] I shall only dwell on the more important points, and add a few observations made since that time.

The locality where we have to look for the lymphatic tissue is at the very base of the tongue, in the glosso-epiglottic fossa. The affection we treat of is not a hypertrophy of the circumvallate papillæ, which were erroneously by some writers regarded as the seat and source of the disease. The lymphatic tissue is situated back of and below the papillæ, which may be hidden and covered by the growth, if it is very prolific, but which are not themselves diseased.

The hypertrophy is, contrary to adenoid vegetations and enlarged faucial tonsils, generally seen in adults, and most easily discovered by the laryngeal mirror. If the growth is excessive, it comes in contact with the epiglottis, sometimes overlapping its free edge and seriously interfering with its free movements.

The chief symptoms we notice in such patients are as follows:

1. The sensation of a foreign body, or of pressure in the throat. Everything imagination can think of, patients believe to be lodged in their throats. To remove this sensation, frequent attempts at deglutition are made, the so-called empty swallowing, whilst there exists no actual interference with the partaking of food. Some cases of globus hystericus find their explanation in the presence of hypertrophic glands.

2. Interference with speech and singing voice. When the enlarged tissue comes in contact with or impinges on the epiglottis, the latter is exposed to friction, and greater exertion is required to produce a sound. The natural consequence is, that patients easily become hoarse, or that their voice is weak, breaks down often and suddenly, and loses its clearness.

3. The lymphatic follicles sometimes become diseased in a like manner as we see in follicular tonsillitis, when the patients experience actual pain.

4. Some writers have observed radiating pains between the shoulder-blades, in the larynx, trachea, etc. One of my patients had shooting pains on each side of the throat, extending toward the ear.

5. Cough is a very frequent and important symptom. It is either a violent, almost incessant, or a spasmodic cough. Especially the latter often gives rise to great anxiety on the part of the patient or his relatives, on account of the fear of pulmonary disease. It is probably due to the friction of the epiglottis and the tongue against each other during their movements.

6. A few cases of asthma have been reported cured by destruction of the hypertrophic follicles.

The above six symptoms were enumerated in my essay of last year. To these we must add two more, which I had occasion to observe since that time, viz., slight bleeding and formation of an abscess. The bleeding occurred in a woman who complained of a harassing cough disturbing her night's rest, and of bloody sputa during the last three months. Examination revealed enormously hypertrophied follicles impinging upon the epiglottis, and minute extravasations of blood at the tip of some of the most prominent follicular glands. The formation of an abscess in a large mass of follicular tissue was seen in a man who expectorated a small teaspoonful of pus tinged with blood, every four to six weeks during the preceding year. Before this event took place, he felt a fulness and slight soreness in his throat, interfering with deglutition, which symptoms immediately ceased afterward. Inspection, which took place one day after the discharge, showed a ragged, irregular condition of the lymphatic tissue, and one large mass on the right side of the base of the tongue, which had formed adhesions with the lingual surface of the epiglottis. Drops of pus exuded from the top of this mass, and, when the galvano-cautery was applied, the electrode could be seen to enter a small cavity.

The treatment of this affection consists in the destruction of the redundant tissue. If small and

[1] Medical Record, December 17, 1887.

soft, applications of Lugol's solution in different strengths may suffice; if larger and denser, stronger caustics are required—for instance, chromic acid, Vienna paste, etc. The best remedy is the galvano-cautery, which is applied in a similar manner as in hypertrophic tonsils. If there is a lobular mass present, which can be engaged in a snare, I am in the habit of using my irido-platinum cautery snare. The wire used with this snare is an alloy of iridium and platinum, having more elasticity and resiliency than platinum alone, and resembling steel wire. It was originally designed for the removal of posterior turbinated hypertrophies of the nose, as described in the *Medical Record*, March 17, 1887, but I found it also very useful for many other purposes, especially in cases in which the softness and flexibility of the platinum wire render operations difficult—for instance, the removal of mucous polypi in the nasal cavities, of anterior turbinated hypertrophies, pedunculated growths in any cavity, etc.

In conclusion, I would state that I have endeavored to present a series of pathological conditions interesting alike to the general practitioner and specialist, and I hope that I may have succeeded in bringing forth all the practical points in a practical manner.

OPERATIVE PROCEDURES IN HYPERTROPHY OF THE PROSTATE.[1]

BY R. D. WEBB, M.D.,
OF BIRMINGHAM, ALA.

CURATIVE measures in hypertrophy of the prostate received but little attention by the older masters of surgery. It was looked upon as a natural sequence of age, and by many regarded as a conservative effort of nature to avoid stillicidium.

Mercier, to whom we are indebted more than to any other surgeon for directing attention to this trouble, commenced his studies of the subject in 1836, and published his *Researches* in 1841. Based upon the fact,—to which he was the first to give prominence,—that a large proportion of cases of obstruction of urine from hypertrophied prostate was due to median enlargement, he instituted his operation of punching an artificial urethra through this median obstruction; but it was not until within the present decade that his labors and operation were generally known. Dr. J. W. S. Gouley, after visiting France, where he met Mercier, introduced his operation into the United States as late as 1878, and he is the only one, so far as I am aware, who has performed it in this country.

These *Researches* of Mercier, and a knowledge of the fact that he had relieved over four hundred cases by his operation, without serious results, a few fortuitous instances in perineal and suprapubic lithotomy, with accompanying enlarged prostates, in which the median bar had been divided, or intravesical pedunculated outgrowths removed incidentally, opened up to the minds of surgeons hope of relief, even in the advanced stages of hypertrophy of the prostate; and the last decade has witnessed a decided advance in the treatment of this former opprobrium of medical science.

Retention of urine being a prominent feature of hypertrophy of the prostate, it was natural that relief should be sought in the line of retention from strictures of the urethra, which had long been familiar to surgeons. Hence the first efforts at relief were in *punctures* of the bladder, which had for their object only relief of the retention, and did not aim at permanent relief. These were made (1) by the canula or aspirating needle into the bladder above the pubis, (2) by the rectum, or (3) through the gland itself, and (4) suprapubic incision and puncture.

The first two need only to be mentioned as they aimed only at temporary relief.

Puncture through the gland itself.—Mr. Reginald Harrison, at the British Medical Association, Liverpool, 1883, said:

"I tapped the bladder from the perineum through the enlarged prostate, quite independent of the course of the urethra. A canula was retained in this position for two months, with great comfort to the patient. He was eighty years old, but completely recovered and lived for several years; and in this I include the acquisition of the natural and unaided use of his bladder" (*Medical Record*, January 21, 1888).

This is similar to the forced catheterism practised by John Hunter and Sir Everard Home, but "abandoned as uncertain and dangerous."

Mr. Harrison himself, speaking of this method of puncture, before the British Medical Association in August 1885, says:

"I must admit that, following the practice of Syme and to some extent of Edward Clark, I have decided preference for an incision through the perineum on the twofold ground of safety and comfort" (THE MEDICAL NEWS, August 18, 1883).

Suprapubic incision and puncture.—Sir Henry Thompson, in a communication to the Royal Medical and Surgical Society (*British Medical Journal*, June, 1879), suggested an opening into the bladder by suprapubic incision and puncture. He thus describes the method:

"A curved hollow sound being introduced into the bladder, the point was made to project against the wall of the organ just behind the symphysis. A small incision being then made, the end of the staff was sought with the finger and the bladder carefully punctured; care being taken not to make the incision too large so as to avoid the escape of urine by the side of the tube to be introduced. A gum-elastic tube, having a shield

[1] Read before the Southern Surgical and Gynecological Association.

like that of a tracheotomy tube, was then passed into the end of the sound, and thus introduced into the bladder."

Mr. Harrison, in speaking of the different methods of puncture of the bladder for the relief of retention, in the Lettsomian Lectures, before the Medical Society of London, January, 1888, says:

"Excellent in design as these proceedings are, they appear to me to fall short in an important respect—in not dealing with the cause of the obstruction. Two of these measures (suprapubic and per rectum) are open to objection on the ground that these artificial canals are inconveniently placed as permanent vents, for it would seem desirable that the urethra should, as far as possible, be utilized, and the external opening for the escape of the urine be dependent" (*Medical Record*, January 11, 1888).

But none of these methods of puncture is now in favor. The surgery of the present day demands more permanent relief by removal of the cause.

The Mercier operation.—The pioneer in the more radical processes was Mercier, of Paris. He was the first to recognize fully the important fact that a large proportion of cases of obstruction to the passage of the urine in these cases was due to an obstructing bar or enlargement of the median portion near the neck of the bladder, often without any serious enlargement of the lateral lobes. With this fact in view, he devised his operation of punching through this obstructing bar a channel, or artificial urethra. The operation was performed by an instrument resembling a fenestrated lithotrite. The beaks of the blade were shorter, and the curve more abrupt, as in the Mercier curve of the Benas gum catheter. The edges of the male blade were smooth instead of striated, as in the lithotrite, so that in passing through the fenestrum of the female blade it made a clean-cut channel through the obstructing bar, which was held between the beaks. "The operation, despite the fact," as we are informed by Dr. Gouley (*Lancet*, July 17, 1880), "that its originator had performed it upward of four hundred times with excellent success, and without the occurrence of abundant, much less fatal, hemorrhage, has not been looked upon with confidence." This, no doubt, arises from the difficulty of nice differentiation in the character of cases, and the conservative spirit of the past, which tends to delay operative interference in these cases as long as possible. The operation is suited only to those cases (for which it was designed by its inventor) in which the obstruction is from a bar or band at the neck of the bladder, and "should be limited in these," says Dr. Gouley (*Amer. Surg. Assoc.*, 1885), "to cases in which the obstructing bar is not exceeding one-half or three-quarters of an inch in thickness."

Dr. Gouley has somewhat modified Mercier's instrument. In an article read before the Surgical Association, 1885, he thus describes his modification:

"On account of the difficulty which I have experienced with Mercier's prostatectome in surmounting from behind forward the urethro-vesical obstruction with the male blade, I devised a prostatectome, of which the following is a brief description. The instrument resembles an ordinary modern lithotrite. It consists of a male and female blade, the one sliding into the other. The male blade is hollow, its sides are vertical, and its superior portion a little rounded. It is welded to a tubular shaft, in the centre of which is a long needle worked by a button at the proximal extremity of the handle. The object of the needle is to transfix the prostatic valvule or tumor, and hold it in position from the moment it is seized till it is cut and extracted. The beak is hollow to receive the piece of valvule."—*Gaillard's Journal*, July, 1885.

The principal advantage this instrument has over that of Mercier's is in the angle of the beak with the blades. In Gouley's instrument it is less abrupt (Mercier's being almost rectangular), and thus passes over the obstructions with greater ease. It is also lighter, and the needle adds an additional safety in retaining and extracting the incised portion of the obstruction.

Bottini's operation.—Closely allied to Mercier's method of punching an artificial urethra is the method of Bottini, of Pavia, which he states he has followed for ten years (THE MEDICAL NEWS, Feb. 11, 1888). He formed an artificial urethra by means of a galvano-cautery. The operation has been termed thermo-galvanic prostatectomy. It consisted in producing an artificial urethra by means of galvanic cautery instead of the punching process of Mercier.

In one of the cases reported, a man of sixty-eight years was restored to complete health, with full functions of the bladder, in three months. In another — Dr. Musatti—the catheter was withdrawn on the fifth day, and the patient left his bed two days later. The result was great improvement in health, and micturition every five or six hours. Dr. Musatti declares the operation less painful than cauterization of the prostatic urethra with nitrate of silver. This may be used not only for the removal of the obstructing bar at the neck of the bladder, but also where the obstruction is from the enlarged lateral lobes. This gives it a wider range of application than the Mercier process. While it has features which recommend it in certain cases, it is not without danger, and has not been used in a sufficient number of cases to warrant its general introduction. It is better thought of in Italy and Germany, where it has been more often used than in this country.

Newman's method.—Dr. Robert Newman, of New York, claims to have used electrolysis, or thermo-galvanic absorption, with a good degree of success. The instrument consists of a smooth sound with a

fenestrum at its lower extremity. At the opening is a piece of platinum wire, in connection with a galvanic battery. The current is kept up only for a few seconds, and repeated at intervals of three to five days. This does not destroy the tissue, as in the process of Bottini, but only promotes absorption of the enlarged gland. It is devoid of danger, and may be used even in the earlier stages of the disease. The principle here is somewhat different from electrolysis in strictures. The absorbent action is brought to bear upon glandular instead of cicatricial tissue, and we may reasonably expect a better result than in strictures.

. I may here refer to one other method of the use of galvanism. In my paper before the Alabama Surgical and Gynecological Society, last year, I said:

"Electrolysis by puncturing the gland itself by a suitable galvanic needle has not, so far as I am aware, been tried; but from the well-attested success of this method in other tumors, it would seem worthy of the attention of some bold innovator."

This method has been since then tried by Casper, of Berlin. At a recent meeting of the Berlin Medical Society he reported four cases treated in this manner. The needle was inserted in three points in the gland *per rectum*, and a current of from twelve to fifteen milliampères used for fifteen minutes, the needle being carefully insulated to prevent injury to the other parts. Two were much improved; in one the result was negative, and in the other there was injury from defective insulation of the needle (THE MEDICAL NEWS, June 16, 1888).

Perineal prostatotomy and prostatectomy.—Sir Henry Thompson had practised digital explorations of the bladder through perineal incisions for the removal of tumors of the bladder. This naturally led to perineal prostatotomy and prostatectomy, as by this route either the obstructing bar at the neck of the bladder could be incised, or the intravesical pedunculated outgrowth could be reached and removed with the scissors or the snare.

This was an advance upon the Mercier and Bottini operations, as it enabled the operator, by digital exploration, to make a more certain differentiation of the case; and at the same time relieve by free drainage the cystitis, which is an almost constant accompaniment of these cases.

Dr. Gouley seems to have been the first to recommend this method. In his *Diseases of the Urinary Organs* (1873), after describing the method of perineal incision for the relief of retention, under the head of "Ablation of Median Prostatic Outgrowths" he says:

"the surgeon should then endeavor to give permanent relief by a procedure which will probably not add greatly to the dangers of the preceding step. He should first explore the prostate through the artificial opening, and if he discover a median outgrowth, or isolated tumor, he should dilate the prostatic sinus, or incise the prostate laterally, and enucleate the tumors, or if there be a median outgrowth excise it; but the better plan is to remove it by means of a small wire écraseur."

Dr. Lardiner, of Leipsic, was led by an accidental seizure and removal of a pedunculated middle lobe in operating for stone, to this same method.

"At first the author was vexed with the unintentional interference with the prostate, but when he saw that good effects followed he was led to believe this was the proper treatment of this class of hypertrophied prostates. He afterward repeated the process, confining himself to the forceps in removing the pedunculated enlargements (*Annals of Surgery*, 1887, p. 433).

Reginald Harrison frequently used this method of perineal prostatotomy and prostatectomy, and preferred it to all others. He says:

"so far I have been able to do all I desired in the way of removing more or less of the obstructing prostate by proceeding from the perineum" (*Med. Record*, January, 1888).

Prostatectomy from the perineum has this advantage: It permits a direct digital exploration of the parts, and thus we are enabled to judge definitely whether the obstruction is from a band or bar at the neck of the bladder, an intra-vesical pedunculated outgrowth, or a general enlargement of the gland; and we may incise the first with the bistoury (Thompson and Harrison); the second may be seized with the forceps (Lardiner), or removed with the scissors (Harrison and Thompson), or seized with the galvano-snare (Gouley and Lang); and the third incised with the bistoury, and a drainage tube inserted (Gouley and Harrison).

Suprapubic prostatectomy.—The revival of suprapubic lithotomy, and the safety with which the bladder can be opened by suprapubic incision, suggested this as another method of relief in prostatic troubles. The operation consists in opening the bladder above the pubes in the usual manner and severing by snare, the scissors, or the forceps that part of the enlarged prostate which prevents the outflow of the urine. Dr. McGill has practised this method in three cases with the best result (THE MED. NEWS, December 10, 1887). In the *Med. Record*, September 23, 1888, there is a report of two cases treated by suprapubic incision, in which Dr. Atkinson removed the protruding enlargement by enucleation, after incision of the mucous membrane, having first removed a small pedunculated growth with the scissors.

Dr. Hunter McGuire, at the Congress of American Physicians and Surgeons (Washington, September, 1888), spoke of suprapubic cystotomy for the purpose of removing intravesical outgrowths

of the prostate, and described his method of leaving a permanent fistulous opening above the pubis as a means of keeping the bladder thoroughly emptied. In the case referred to, the patient was not only relieved of the troublesome cystitis, but acquired voluntary control of retention and expulsion of his urine.

Thus it is seen we have a variety of methods for relief. Each of them may have advantages, under certain conditions peculiar to itself, and by a careful differentiation of cases, and a prudent selection of the method suited to each case, we may hope to give relief, more or less permanent, in many cases heretofore abandoned as without hope.

What is now needed is an accurate differentiation of cases, a prudent selection of the process suited to each case, and judicious determination of *the time* when it may be proper to interfere by operative procedures.

Much has already been done in the line of differentiation. Mercier, to whom too much credit cannot be given, made a long stride in the right direction when he emphasized the fact, that to median obstruction, frequently without any serious enlargement of the lateral lobes, was due a large proportion of cases of obstructed urine; and his operation was wisely conceived for relief of this condition. He not only emphasized the existence of median obstruction, but by means of his rectangular, short-headed catheters and sounds, did much in determining the situation, form, and size of other obstructions, thus paving the way to a more accurate differentiation of cases.

The varieties may thus be classified:

(1) *General enlargement:*
  (*a*) Of one lateral lobe.
  (*b*) Of both lateral lobes.
(2) *Median obstruction:*
  (*a*) Sessile tumors.
  (*b*) Bar, or valvule at neck of bladder.
(3) *Intravesical outgrowths:*
  (*a*) Pedunculated outgrowths of median portion.
  (*b*) Prolongation of lateral lobes.

These varieties may occur separately and distinct, or they may be combined one with the other. General enlargement, while it may be the prominent characteristic, may be (and frequently is) accompanied by median obstructions—extra- or intra-vesical—or it may occur without these median complications; while upon the other hand, the median enlargement may be the main or sole trouble.

In the extra-vesical median, sessile enlargement, the submucous tumor is at some little distance from the urethro-vesical orifice and raises the connecting tissue (commissure) of the lateral lobes more obtusely, while in the bar, or valvule, the tumor being located nearer the vesico-urethral os, and from the absence of resistance, raises the mucous fold more acutely and near the neck of the bladder.

The intra-vesical varieties may be a prolongation of the lateral lobes, one or both, into the bladder; or the median portion may protrude into the viscus, as a pedunculated tumor.

For a wise application of the different methods of operation, we should, as near as possible, differentiate between these varieties, so as to select the operation suited to each variety.

(1) We may infer something from the clinical history of the case. If the patient is young (from 54 to 60) with decided obstruction, and no amount of effort will relieve the bladder, we would infer a median enlargement, with valvule at neck of bladder or a pedunculated intra-vesical outgrowth. If the obstruction has been very gradual in its approach, and the patient is still able at advanced age (seventy or more) to empty the bladder after patient effort, we may infer that the enlargement is general. This inference is the more certain if the patient has a stillicidium, or kind of siphonage of the urine, when the bladder becomes distended. This stillicidium is often present when the bladder is over-distended, and the fact of retention is overlooked.

(2) But our main reliance is upon physical examination. This is made per rectum or by the urethra. By careful digital examination, per rectum, we may determine the size, hardness or softness—smoothness or roughness—whether one or both lobes are enlarged, whether the enlargement is general, or whether there is an absence of general enlargement, and hence the inference that the obstruction is median or an intra-vesical outgrowth. If now with the sound or catheter (soft-gum catheter of Benas, with Mercier curve preferred) we find the constriction commences at the apex of the gland, and continues evenly until it enters the bladder; and if in *withdrawing* the catheter we find the *grasping* of the catheter continues steadily until it passes the apex, which it does with a kind of jump, we have full confirmation of the diagnosis of longitudinal or general enlargement.

But, in a general enlargement, there may be complications. In addition to the general enlargement we may have a sessile tumor, valvule, or intra-vesical pedunculated outgrowths, or extensions of the lateral lobes into the bladder. The sessile median enlargement combined with lateral general enlargement, may be detected by the increased resistance to the passage of the catheter or sound as we reach the portion of the urethra just before entering the bladder. This may be noticed either in introducing or withdrawing the catheter. The pedunculated intra-vesical outgrowths, and intra-vesical prolongation of

the lateral lobes whether existing with or without general enlargement, are to be determined by the Mercier rectangular sound, or by Dr. Gouley's cysto-pylometer. This instrument, which is a modification of Mercier's sound, is thus described by Dr. Gouley:

"The beak of the instrument is nearly rectangular and one inch in length. The shaft is in two longitudinal segments—the male segment sliding over the female and being flat at its vesical end to come in contact with the corresponding flat surface on the inner side of the beak of the female segment, and designed to grasp the valvule or bar."

The instrument when closed resembles a metallic sound with a short, rectangular curve. It is introduced closed and when in the bladder the beak is turned gently from right to left, and the reverse—noting carefully any resistance it may encounter. If it meets with firm, unyielding resistance on either side, we may infer intra-vesical enlargement of the lateral lobes; but if the resistance is yielding, and changes its relations to the handle of the instrument, we may infer that we have a pedunculated intra-vesical median outgrowth.

We may with a good degree of certainty distinguish between the sessile median enlargement and the crescentic valvule or bar, with the same instrument. The cysto-pylometer being introduced closed, into the bladder, and drawn outward until the beak rests against the intra-vesical orifice of the urethra, the male blade is carefully withdrawn. The amount of resistance by the median enlargement is estimated fairly well by the resistance met with in withdrawing this blade. After the resistance ceases, the male blade is gently carried toward the bladder again. If it is a sessile median enlargement, the blade will, with a continuous resistance, pass into the bladder; but on the other hand, if it is a valvular bar, the beak will be arrested by it, and the obstruction may be grasped between the beaks of the male and female blades, and its thickness estimated by the amount of separation of the blades, by the scale on the handle of the cysto-pylometer.

Electro-cystoscopic explorations, where the urethra will admit of the introduction of the instrument, may also be brought to our aid, and we may be able with this instrument to differentiate intra-vesical outgrowths of the prostate from intra-mural vesical tumors.

Thus by inquiry into the clinical history of the case, careful digital examination per rectum, exploration of the urethra and bladder by the catheter and the cysto-pylometer, we may gain a fair idea of the character and position of the obstruction. This being determined, we may then select the surgical process suited to the case.

If the obstruction is from a general enlargement of the gland, we may use the Bottini galvano-cautery; or galvano-absorption, as practised by Dr. Robert Newman; or perineal prostatotomy. If, upon the other hand, the examination shows a general enlargement, with intra-vesical outgrowths, we may resort to suprapubic prostatectomy combined with urethral prostatotomy by means of an instrument similar to the urethrotomes used in dividing strictures of the urethra; or perineal prostatotomy as practised by Mr. Harrison. Or in these complicated cases, we may use the method of McGuire, and instead of combining perineal or urethral prostatotomy with supra-pubic prostatectomy, be content with a supra-pubic fistula for the exit of the urine.

But if we determine that we have a median valvule or bar as the obstructing cause, the Mercier operation is plainly indicated. Or if the case is one of intra-vesical outgrowth with but little general enlargement, the supra-pubic operation is the method indicated.

Another factor of success in these cases, is the *time* at which surgical interference should be resorted to. The remark of Mr. Harrison, "that no operation should be thought of so long as the catheter can be introduced," should be modified. When we have at our command methods that may be used with safety in the earlier stages, when the cases are carefully differentiated, and relieve the patient of years of annoyance or suffering, I can see no good reason why we should not use them. And probably in this *timely interference* is where we may expect most in the relief of prostatic troubles. The conservative spirit which has guided our actions to the present, may be in danger of going too far, and leaving undone what might be well done. The early use of the process of Mercier, and the milder one of Newman, are well worthy of consideration upon properly selected cases, and the future will doubtless see them often resorted to before patients are worn out by long suffering, and reduced to the last extremity, when the system is badly prepared for any operation.

The operation of Bottini, too, with well-constructed instruments, would seem to be preferable to a life-long suffering or premature death. This operation, which has not been well received in this country, is better thought of in Italy and Germany. Nussbaum, while condemning almost all other forms of surgical relief, approves the galvano-caustic method of Bottini.

Even perineal and supra-pubic prostatectomy, in this day of improved surgical technique and antisepsis, may well be resorted to in the earlier periods, rather than an apathetic contemplation of a life of suffering, and the gradual and sure approach of a condition, in which, *as a last resort*, these measures are attempted with but little hope of success.

MEDICAL PROGRESS.

Treatment of Acute Coryza.—DR. FRANK HAMILTON POTTER, of Buffalo, recommends the following treatment for this affection:

If the cold comes on toward evening, a hot bath should be taken, followed by the exhibition of $\frac{1}{100}$ to $\frac{1}{80}$ of a grain of sulphate of atropia, and the patient well wrapped up in bed. A word of caution is necessary in regard to the use of the atropia. Some people are very susceptible to its influence, and when given for the first time a much smaller dose must be used—say $\frac{1}{250}$ to $\frac{1}{200}$ of a grain. When found to disagree, a full dose of the sulphate of quinine, about ten grains, may be substituted. During the next day the nose and upper part of throat should be thoroughly washed out with a warm alkaline spray; or, still better, with a douche, by means of the posterior nasal syringe; the turgescence of the nasal tissues contracted by means of cocaine; and, finally, the entire surface covered with a coating of an unirritating oil. The *oleum petrolina* he has found to be the best for this purpose. This should be done about three times in the course of the day. If the cold is first noticed in the morning, the process should be reversed; the local treatment given during the day and the general treatment at night. From experience he was able to report that, by this method, colds that generally last from ten days to two weeks can be limited to about two days. The discomfort after that is so very slight as not to be considered. He does not propose this as an infallible method, but where it fails it will usually be found that there is some intra-nasal chronic disease, or else some constitutional disorder which makes the attack of extraordinary obstinacy.

Lately, Dr. F. Cardone, of Naples, has contended for the parasitic nature of acute coryza, stating that its morbid process is analogous to that of pneumonia. He has found in the secretions the *streptococcus pyogenes*, the *staphylococcus aureus et albus*, and, in still greater numbers, the *diplococcus* of Fränkel and the *pneumococcus* of Friedländer. If he is correct, we can, perhaps, understand the great benefit resulting from the early and continued cleaning of the parts, such as the above treatment advocates. On the other hand, if a cold is caused by the paresis of the nerve-centres governing the vaso-motor phenomena of the upper air-tract, we can also understand how the counter-shock of the hot bath and atropia treatment, together with local depletion, so rapidly subdues the inflammatory action and restores the patient to accustomed health.—*Buffalo Medical and Surgical Journal*, January, 1889.

Employment of Iron in Diseases of Children.—DR. H. GILLET remarks that to the fourth or fifth year, one should guard against the use of medicaments and above all against the use of iron preparations. And yet two of these would form an exception, namely, the protoiodide and the perchloride of iron. The first of these is, properly speaking, not an iron preparation, but rather an iodide, and is used in the treatment of scrofulous affections; the second is used in hemorrhages and in conditions of a generally grave nature, such as typhoid fever, diphtheria, etc.

Iron preparations, to be acceptable to children, must first have a pleasant taste; secondly, not derange the digestive functions; and thirdly, admit of being administered in small bulk. This last condition is easily attained, since the preparations in question act in very small doses.

Thus to a child from eight to ten years, one of the following powders given once a day, will be found to be sufficient:

℞.—Subcarbonate of iron,
Powdered rhubarb,
Sugar flavored with vanilla, } āā 2 grains.
Mix with some preserved fruit.

Iron preparations appear under two forms, soluble and insoluble. The insoluble in the powdered form as: the subcarbonate reduced, and saccharated carbonate of iron, etc., are easily mixed with any disguising substance. Pills being generally refused, they must either be administered in their natural state or in the form of chocolate tablets:

℞.—Reduced iron . . . . . 3 grains.
Chocolate . . . . . ℥x.

Make one tablet—administer during the day a quarter or a half a tablet according to age of child.

The soluble preparations are numerous; those to be preferred are the lactate, the citrate, the chloride, and the tartrate of iron and potassium. The lactate is less irritable to the stomach than the citrate and can be administered in wine or liquor as follows:

℞.—Citrate of iron . . . . . 30 grains.
Malaga wine . . . . . ℥iij.

One teaspoonful once or twice daily.

The perchloride, if it were stable, would have the preference over all other preparations, the syrup containing two grains of the iron, in ℥v of the syrup.

The chloride can be administered alone or as in the following formula:

℞.—Solution of chloride of iron . . ℥iss.
Spirits of ether . . . . ℥iij.

Five to ten drops in sweetened water, to be taken through a tube.

The tartrate of iron and potassium can be administered in various ways:

℞.—Tartrate of iron and potassium
Cinnamon water . . . } āā ℥j.
Simple syrup . . . . . ℥iv.

One to two teaspoonfuls three times daily.

Or,

℞.—Tartrate of iron and potassium . 30 grains.
Syrup of bitter orange-peel . . ℥ij.
Muscatel wine . . . . ℥viij.

A small wine-glassful after each meal.—*Revue Thérapeutique*, December 20, 1888.

The Operative Treatment of Hydrocele.—The last number of Professor Bruns's *Beiträge zur klinische Chirurgie* contains a paper on the "Operative Treatment of Hydrocele and its Ultimate Results," in which DR. HERTZBERG, of Tübingen, endeavors to prove the superiority of incision over injection by a record and analysis of forty-six cases,

in which Volkmann's radical operation was performed. The youngest patient was twelve years of age, and the oldest fifty-six years; in six cases the hydrocele affected both sides of the scrotum. The operation in each case was performed with full attention to antiseptic details. The vaginal cavity was washed out with a weak solution of corrosive sublimate; a drain-tube of medium size was passed through the cavity, and brought out through a counter-opening at the lower part of the scrotum, and the seat of operation and the surrounding parts were finally covered by a dry dressing of wood-wool. Professor Bruns practises partial excision of thickened indurated or superfluous tunica vaginalis, but holds that total excision of this membrane is not required, save in very exceptional cases. Care was taken to relieve the vaginal cavity of all products that were supposed to be associated with the disease, and in a case in which such morbid conditions existed, deposits and growths were removed from the tunica vaginalis, hydatid and other cystic growth from the testis or epididymis.

In thirty-three cases recovery took place without any signs of local or general reaction. In eight cases there was severe general reaction with subjective disorder and prolonged fever. Such conditions which, however, are now but very rarely observed, are the result of interference with primary healing by effusion of blood into the vaginal cavity, of inflammatory œdema of the scrotum, of swelling of the testis, or of suppuration in the perineum or the anterior abdominal wall. In a large majority of the cases collected by Hertzberg the drain-tube and sutures were removed on the fifth or sixth day, and the patient was able to leave his bed at the end of the first, or the beginning of the second week.

The average duration of the stay in hospital was a little over sixteen days. In this respect Volkmann's operation seems at first sight to compare unfavorably with injection of iodine. The usual duration of hospital treatment by the latter method is from eight to ten days, but, it is pointed out, injection is very often followed by tenderness and swelling of the scrotum and effusion into the vaginal cavity, which may last for weeks, and even for months.

All the patients treated by incision and drainage at Tübingen were discharged as cured, and the primary results were all very favorable. By subsequent inquiry and observation Hertzberg has made out that the benefits derived from the treatment have been maintained, and that forty-five out of forty-seven hydroceles treated by cutting operation have been permanently cured. By comparing tables, derived from different sources, of carefully recorded and long-observed cases of hydrocele treated by incision and injection, he finds that the relapses after the former treatment constitute from three to four per cent. of the total number of cases, whilst those after treatment by puncture and injection of iodine amount to eight per cent. In conclusion, Hertzberg expresses it as his opinion that incision is the most rational method of treating hydrocele, especially with regard to the certainty of obtaining a permanent cure, and that in future it will be more frequently practised, as the appreciation of the value of antiseptic surgery becomes more widely spread.—*London Medical Recorder*, Dec. 20, 1888.

Oil of Turpentine in Epistaxis.—Dr. Ernyei (*Pester Presse*, No. 14) treated a severe case of bleeding from the nose, which had resisted treatment with ice, ergotine, digitalis, etc., with tampons saturated with oil of turpentine, and had the satisfaction of stopping in a few minutes an epistaxis which had lasted eight days.—*Deutsche med. Wochenschrift*, December 13, 1888.

Cocaine in the Treatment of Whooping-cough.—To diminish the violence of whooping-cough, painting the pharynx and tonsils four times daily with the following mixture is recommended:

Chlorhydrate of cocaine . .	grs. xv.
Water	℥ v.

—*Journal de Médecine*, December 16, 1888.

Three Cases of Railway Shock.—At a recent meeting of the Vienna "Medizinisches Doctoren-Collegium," Prof. Benedikt brought forward three patients who had suffered from different degrees of the so-called railway shock. The first of these patients, immediately after the accident, presented severe nervous symptoms, such as headache, giddiness, sickness, impaired mental faculties, etc. The two other patients became attacked with the nervous disturbances some time after the shock; one of them suffered from headache and giddiness, which hindered him from doing his regular work. It was not until three years later that his field of vision became impaired, first only for colors, and later on also for white light. At a later stage, examination with the ophthalmoscope proved the presence of neuro-retinitis. In the case of the third patient, a number of severe nervous symptoms supervened some time after the shock. The speech of the patient was scarcely intelligible, though the tongue was not paralyzed; but his faculties of recollection were impaired. Paraparesis with simultaneous augmentation of the reflexes came on, viz., ataxia hemilateralis, which was characterized by the fact that the patient invariably fell toward the right side when he shut his eyes. Prof. Benedikt remarked that in the recent cases of railway shock a number of subcutaneous injections with a two per cent. solution of carbolic acid, the application of the electrostatic method as well as a number of *points de feu*, could remove the nervous disturbances under consideration, and prevent those severe symptoms which were to be observed in the two last-mentioned patients.—*Medical Press*, December 19, 1888.

Treatment of Diarrhœas.—DR. RABOW states that lactic acid and talc, two of the best remedies for diarrhœas, are highly recommended by two well-known French physicians.

Lactic acid was first used with success by DR. HAYEM in the green diarrhœas of infants; the little patients receiving, every fifteen minutes, a teaspoonful of a two per cent. watery solution of this preparation. Later on Dr. Hayem tried the same remedy in the obstinate chronic diarrhœas of the adult, to whom he administered with the best results, three times daily, a tablespoonful of the following mixture:

℞.—Lactic acid	grs. xxx.
Water	℥ iij.
Simple syrup	℥ v.—M.

DR. SEVESTRE also administered a teaspoonful of this preparation, five or six times daily, without observing the slightest unfavorable symptoms. In the so-called bilious diarrhœa, lactic acid was found useless, only large doses

of bicarbonate of sodium acting effectively. Later on DRS. SÉZARY and AUNE tried the remedy in the diarrhœa of tuberculosis, administering thirty grains of the acid to a four ounce mixture, and if this did not prove active enough, ninety and one hundred and twenty grains to a four ounce mixture. This quantity was taken in tablespoonful doses within twenty-four hours. The evacuations were diminished in frequency, and became normal on the fourth day.

Another remedy has been recently recommended by DR. DEBOVE, namely, magnesium silicate, also known by the name of talc.

This preparation was given in large doses, producing the most favorable results, especially in the diarrhœa of tuberculosis.

Another valuable remedy is the acorn-cocoa as prepared by DR. MICHAELIS. Added to milk it forms a valuable nutriment, overcoming the diarrhœa of malassimilation. In the chronic diarrhœa of adults and children it must be mixed with water *only*.

In acute diarrhœas, cardamom seeds, a remedy which can be found in almost every household, have been used with advantage. Children as well as adults may chew the contents of one or two capsules.—*Therapeutische Monatshefte*, December, 1888.

The Cause of Death in Acute Pneumonia.—LIEBERMEISTER, in the course of a paper on a series of cases of acute croupous pneumonia, has expressed the view that death is generally due to pulmonary œdema of the non-infiltrated portions of the organ; this œdema he attributes to cardiac failure. The fever, he says, tends to produce degeneration of the heart muscle and functional insufficiency, while the heart has to act against an increased resistance, due to compression of the bloodvessels by the infiltrated lung; the right heart, acting under these unfavorable circumstances, fails, and the first symptom of its failure is the pulmonary œdema above mentioned. —*British Medical Journal*, December 29, 1888.

Cardiac Cyanosis.— DR. A. FALLOT publishes in the *Marseille Médicale* the results of his exhaustive researches upon cardiac cyanosis, from which the following conclusions are deduced:

1st. Clinicians have up to this date considered the precise diagnosis of the anatomical lesions of cyanosis an impossibility. From observations gathered he found that cyanosis in the adult is the result of a number of small cardiac malformations.

2d. Amongst these cardiac malformations is one which in frequency surpasses all others, it having been found in no less than seventy-four per cent. of our cases; this is the one which the clinician should diagnosticate, and having done so, his chances of future errors will be limited.

3d. This malformation constitutes a true anatomical pathological type represented by the following four conditions: 1st. Narrowing of the pulmonary artery. 2d. Interventricular communication. 3d. Deviation of the orgin of the aorta to the right. 4th. Hypertrophy, nearly always concentric, of the right ventricle.

4th. To attribute cardiac cyanosis to the persistence of the foramen ovale, would be in open opposition to the immense majority of facts observed; the communication of two small foramina, existing alone, without any other cardiac lesion, does not produce cyanosis.—*Revue de Thérapeutique*, December 15, 1888.

Convenient Formulas for the Administration of Creasote.— DR. KEFERSTEIN (*Th. Mtsch.*, 1888, No. 9) gives some very good formulas for the administration of creasote. The one at first recommended by Dr. Bouchardat, and later on by Dr. Fräntzel, has been modified by the author, as follows:

℞.—Creasote . . . . . gr. xx.
Alcohol . . . . . ʒvj.
Cinnamon water . . . . ℥iij.
Cinnamon syrup . . . . ʒvj.—M.
One teaspoonful three times daily.

For the pill-form the following is recommended:

℞.—Creasote . . . . . gr. lx.
Powdered marshmallow root }
Purified liquorice . . } āā ʒjss.
Mucilage of gum arabic . . q. s.—M.
Div. pill. No. cxx. Coat with gelatine.
Sig.—One pill three times daily.

In irritative cough and diarrhœa the following is administered:

℞.—Creasote . . . . . gr. xxx.
Acetate of lead }
Opium (pure) } . . . āā gr. v.
Extract of liquorice . . . ʒjss.
Mucilage of gum arabic . . . q. s.—M.
Div. pill. No. 50.
Sig.—One pill three times daily

For children, creasote in the form of the following emulsion seems best adapted:

℞.—Creasote . . . . . gr. xx.
Dissolve in
Almond oil . . . . . ℥j.
Gum arabic . . . . . ʒv.
Water . . . . . ℥iij.—M.
Make an emulsion, and add,
Compound tincture of orange peel gtt. xv.
Oil sugar of peppermint . . ʒj.—M.
One teaspoonful two to five times daily.

For drop doses the author uses the following:

℞.—Creasote . . . . . gr. xlv.
Tincture of cinnamon . . . ℥j.—M.
Fifty drops, three times daily, in half a cup of warmed milk or warmed sweetened water, or Malaga wine, etc.—*Deutsche med. Wochenschrift*, December 20, 1888.

Tuberculosis a Specific Infectious Disease.—An interesting proof of the widespread acceptance of the view of the nature of tuberculosis first forcibly maintained by Villemin, and recently so strongly confirmed by Dr. Koch's discovery of a specific bacillus, is afforded by the fact that in the new edition of Fagge's *Medicine*, Dr. Pye-Smith has classified tuberculosis among "specific infectious diseases," between syphilis and pneumonia. One consequence of this general acceptance has been the growth of a more hopeful feeling with regard to the prognosis of tuberculosis.

Kurlow has conducted some experiments which have a direct bearing on the solution of this question. It is

well known that it is by no means uncommon to find *post-mortem* evidence of cured tuberculosis of the lungs. Twenty-six cases of apical affections of the lungs found at the necropsies of persons dying of some affections other than tuberculosis were tested with the following results: 1. Inoculations made with material obtained from three simple cirrhotic patches in the apices gave negative results. 2. Inoculations made with material obtained from four cirrhotic patches infiltrated with calcareous matter were likewise negative. 3. Inoculations made with material obtained from twelve capsulated caseous patches on twenty-six animals resulted in the development of tuberculosis in twenty of the animals. The experimental results show that in twenty-six suspected cases of tuberculosis of the pulmonary apices, seven only, twenty-seven per cent., were non-infectious.

Bollinger, in common with other observers has found that the milk of cows suffering from local or general tuberculosis may be infectious, but that the infective power is very greatly diminished by dilution. The meat that is to say the muscles, of tubercular cows was not, according to his experiments, infective.—*British Medical Journal*, December 29, 1888.

Pyrodin.[1]—DR. OSKAR LIEBREICH gives the following *résumé* of Dr. Dreschfeld's researches into the action of pyrodin:

1. Pyrodin is a powerful antipyretic.

2. It lowers the temperature very rapidly, the same remaining low for several hours.

3. It is easily administered. It incites skin activity, but no nausea, vomiting, or collapse.

4. Its beneficial action is especially well demonstrated in pneumonia, scarlet fever, and petechial typhus.

5. It is less beneficial in typhoid fever.

6. It acts favorably in migraine and neuralgia, though the number of observations made thus far do not admit of any positive assertion.

7. It should only be administered once in eighteen or twenty-four hours, and only for a few days at a time.

8. It has acted in cases in which other antipyretics failed.

9. The dose for children is from two to four grains; for adults, from eight to fifteen grains.

10. In its action it is more powerful than antipyrin, and antifebrin, being at the same time more toxic than these preparations. This last disadvantage is overcome by the fact that it need not be given more than once in eighteen or twenty-four hours, as its antipyretic effects last longer than those of any other preparation.[2]

11. It lowers the pulse as well as the temperature, and frequently produces diuresis.—*Therapeutische Monatshefte*, December, 1888.

The Lancet, of December 29, 1888, has the following: "Great caution, however, is required in its administration, as it is apt to produce jaundice, followed by anæmia, and even more serious symptoms due to hæmoglobinæmia. Small doses only should be given, and at sufficiently long intervals to enable one to watch any toxic effects."

[1] Pyrodin contains as its active agent *acetylphenylhydrazin* ($C_6H_5N_2H_1C_2H_3O$) a crystalline powder, very sparingly soluble in water.

[2] Later investigations have led Dr. Dreschfeld to conclude that the toxic effects of pyrodin must be well guarded against.

Treatment of Facial Eczema in Children.—DR. E. BESNIER distinguishes three distinct varieties of infantile facial eczema: eczema of lymphatic or scrofulous origin, pruriginous eczema of dentition, and desquamative eczema.

I. *Scrofulo-tuberculous eczema.*—This is treated with lotions of a teaspoonful of Van Swieten's liquor[1] to a bowl of warm water, gradually increasing the quantity of the mercurial liquid. The lotions to be followed by the application of the following ointment:

℞.—Vaseline	℥j.
Calomel	15 grains.

Which in turn is replaced by the following:

℞.—Vaseline	℥ij.
Red precipitate	1 grain.

II. *Eczema of dentition.*—The dental irritation should be overcome by painting the gums with the following solution:

℞.—Cocaine	1 grain.
Bromide of potassium	8 grains.
Water. Glycerine āā	℥iss.

If necessary some bromide of potassium can be administered internally. After this the following ointment should be applied to the gums:

℞.—Oxide of zinc	℥iss.
Vaseline	℥iv.—M.

III. *Pruriginous eczema.*—Should the eczema attack the scalp, the hair should be cut short and the scalp cleansed thoroughly with soap-lotions. In facial eczema the crusts should be softened with warm milk and water, and then the following ointment applied:

℞.—Resorcin	8 grains.
Oxide of zinc	℥iss.
Vaseline	℥iss.

Or,

℞.—Powdered sulphur	℥iss.
Oxide of zinc	℥iij.
Vaseline	℥iij

—*Revue Thérapeutique.*

Naphthol in the Treatment of Itch.—DR. KAPOSI recommends the following formula:

℞.—Naphthol	gr. l.
Green soap	℥vj.
Prepared chalk	℥jss.
Lard	℥j ℥ij.—M.

Apply once a day.

The substitution of lanoline for lard will admit of deeper penetration of the ointment.—*Revue de Thérapeutique*, December 27, 1888.

Sublimate Solutions in Cystitis.—DR. LINDÉN (*Finska läkaresällskapets handl.*, No. 29) recommends injections of sublimate solutions 1 : 75,000 to 1 : 50,000 in cystitis.—*Deutsche med. Wochenschrift*, December 20, 1888.

[1] The formula for Van Swieten's liquor is as follows:

℞.—Bichloride of mercury	5 grains.
Water	℥j.
Alcohol (80 per cent.)	℥j.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JANUARY 19, 1889.

THE REPOSITION AND PRESERVATION OF BONE-GRAFTS.

As is well known, after removal of portions of the skull by trephining or otherwise in time the gap will become occluded by a laminated fibrous substance, whilst those portions of the membrane which are near to the edges of the opening, after the lapse of several months, and more especially in the young, will frequently be found more or less ossified. This membrane is usually ample protection for the cranial contents if the amount of bone removed is not large; but after exsecting so great an area as is sometimes necessary for purposes of exploration or removal of growths or of shattered or depressed fragments, the simple fibrous wall does not afford sufficient protection.

To obviate this, as long ago as 1868 Ollier recommended what he termed "subperiosteal" trephining—that is, the preliminary raising of the periosteum and its careful reposition after removal of the disk or fragments, and thus he was enabled frequently to secure bony occlusion of the trephine opening. Shortly afterward he further proposed the now revived procedure of replacing the entire button or fragments, but after experimenting several times and, in the absence of antiseptics, lamentably failing, he was led to condemn the measure.

Three years ago Macewen, at the time of performing some of his wonderful brain operations, was led to repeat Ollier's experiments, and, with the aid of antisepsis, was as brilliantly successful as Ollier had been unfortunate. He operated by the subperiosteal method, broke the disks into small grafts and planted them upon the dura mater, and then replaced the pericranium. A year later Horsley recommended that the button or other fragments be replaced entire, regardless as to what their size might be. These are now recognized procedures in many cases, but the query arises as to what are the conditions under which replacement, partial or entire, is indicated.

Reposition is indicated where the amount of bone removed is large and in which the wound can subsequently be kept aseptic. Where purulent drainage is expected, either the grafts should not be replaced, or we should be prepared again to remove them upon the first sign of trouble indicating that they had perished and become dangerous foreign bodies in the wound. Buttons or grafts from such palpably septic operations as those upon suppurating mastoid cells or abscesses resultant therefrom should never under any circumstances be replaced.

Again, the mode of replacement of the graft is of importance, for the exact replacement of a tightly fitting graft will effectually prevent drainage, which latter, when indicated, is as important in brain as in abdominal surgery. Therefore, if the button be in one piece it must be notched or broken before replacement, that an ample exit for the catgut or rubber drain may be provided.

The means of preserving grafts from the time when removed until wanted for replacement is another question of great importance. This has hitherto been more or less effectually accomplished by placing them in hot antiseptic solutions, but we have gained best results by simply wrapping the fragments in a few layers of moist aseptic gauze, and placing the whole in a covered dish until wanted. This method could be improved upon by having the fragments wrapped as above and deposited in a jar, dish, or saucer floating upon water maintained at a temperature of 100°–110° in a covered vessel. The proposal of Dr. Dercum, of this city, to place the grafts in sterilized blood serum kept at 100° is logical, but presents great practical difficulties, and could not yield better results than does the above-described method. On the other hand, it is not wise to preserve them in simple boiled water, nor in antiseptic solution, because of the devitalizing effects of those agents. What we require is simply asepsis, warmth, and moisture, and under these conditions the bony fragments will more than retain their vitality until the termination of even the most prolonged operation.

When the grafts are themselves septic—as in compound fractures—but the conditions indicating replacement are present, then, to insure asepsis, the risk of immersion in antiseptic solution must be taken, or clean fragments must be procured from a lower animal or elsewhere and used in their stead.

Our remarks apply equally to all grafts, whether taken from other situations or from animals.

THE APPLICATION OF EXTENSION IN POTT'S DISEASE AND VERTEBRAL INJURIES.

AT the clinic of the University Hospital, on Friday last, Dr. H. C. Wood showed and explained a method of treatment applicable to cases of Pott's disease and to fractures of the spinal column, which he believed to be novel, and which may, upon further trial, prove of great practical importance. Dr. Wood called the attention of the class to the fact that many years ago Prof. J. K. Mitchell treated the cases of Pott's disease by swinging from the head, and that the ordinary treatment by means of the plaster-jacket was an attempt to carry out the indication of extension of the vertebral column. The spinal-jacket, however, as ordinarily placed, fails to produce any continual increase of extension; it simply saves that which has been gained during the few minutes' suspension of the patient. The difficulty with Prof. Mitchell's plan of treatment lies in the fact that very few persons can be found whose strength of neck and lack of general sensitiveness will allow them to be even partially suspended by the head for any length of time; and yet it is claimed that recently in the Orthopædic Hospital great good has been achieved in certain cases by a return to the old treatment with the J. K. Mitchell chair.

Dr. Wood stated that it had occurred to him that the spinal-jacket might be used for the purpose of extension. The chest of a well-shaped man is an inverted cone, and any upward strain upon the jacket would naturally be received, not upon any one point, but upon numerous points upon the surface of the wall.

Dr. Wood, therefore, had a jacket made with loops, from which the patient could be suspended. The making of the loops is very simple: after the first layer of the jacket is put on, a strong linen bandage is placed at the lateral lower edge anteriorly, and then carried directly up, loosely, over the shoulders, and down again to a similar position on the posterior edge of the jacket. The bandage is then reversed, and carried upward and forward and returned until three or four turns of the bandage are loose over the shoulders. The same is done down the other side of the jacket, and then the exterior layers of the jacket are put around the two bandages, up to the top of the jacket. When the whole mass is hardened the linen bandages are so thoroughly incorporated with the jacket that they cannot be pulled out, except by the destruction of the jacket; and above the shoulders they afford a loop to which can be attached a cord or any other device for the purpose of suspension.

At the trial in the clinic, a man with Pott's disease in the lower dorsal region, upon whom the jacket had been placed, was partially suspended in a sitting position. The force of extension, as accurately measured, was seventy-five pounds, and was steadily maintained for four hours without interference with the circulation, without straining the arms, or in any way causing suffering. At the end of the time the patient said he felt more comfortable than before he had been swung.

Dr. Wood also suggested the use of the method in fractures of the spinal column, stating that not only could the patient be suspended for hours, but by securing the loop in the jacket to the head of the bed, and raising the latter at an angle, the weight of the lower segments of the patient's body could be used to extend the spinal column, even during sleep. The force of the extension, of course, could be varied according to the necessities of the case, by lowering or lifting the head of the body. In putting on the jacket a coating of cotton batting should be put between it and the undershirt of the patient.

Since the clinic the case of Pott's disease has been daily suspended for some hours; and he now affirms that not only is he more comfortable in the jacket, but he is now able to move much more freely his left leg, which had been almost completely paralyzed; he can, indeed, lying in bed raise it up and cross it over its fellow.

If future experience should confirm the use of the plaster-jacket, it is evident that by means of a little ingenuity with the wheel-crutch and baby-jumpers much can be gained in the treatment of vertebral caries and vertebral traumatisms.

DR. GEORGE A. BODAMER, of the German Hospital, of Philadelphia, presented on Monday evening, before the German Medical Society of Philadelphia, a case of a young man suffering from a swelling of

the right side of the head and neck, with necrosis of bone, and demonstrated in the discharge from a fistulous opening in the temporal region the presence in enormous quantities of the radiating fungus known as actinomyces. Dr. Bodamer diagnosed the case as one of actinomycosis, and stated that, as far as he knew, it was the first case on record in this country. The details of the case he will publish later. A demonstration of the case was made at Dr. Deaver's clinic at the German Hospital, and the observation was corroborated by Dr. Formad in his morbid anatomy demonstration at the University of Pennsylvania on the following day.

The College and Clinical Record, in its current issue, excuses itself for copying, without credit, an article from our columns and publishing it three months afterward as an *original* article of its own, on the ground that the paper, having been read before a society, was not the exclusive property of any periodical. The article in question was published exclusively in our columns under arrangement with its author, who was duly paid for it, and our ownership of it is fully protected by copyright. Even if this were not so, our contemporary was scarcely more just to its own readers, in giving them as "original" an article which had been published in another journal three months before, than it was to us in copying the article from us without any acknowledgment of the source from which it was taken.

DR. A. L. LOOMIS has been elected President of the New York Academy of Medicine.

THE Chair of Materia Medica and Therapeutics at the Niagara University has been filled by the appointment of Dr. Albert E. Persons, of Buffalo. This is the Chair recently made vacant by the decease of that brilliant young teacher and author, Dr. Frederick R. Campbell.

M. PASTEUR has resigned the Secretaryship of the Académie des Sciences on account of ill-health.

THE Royal College of Surgeons of England, by a vote of 21 to 2, has passed a resolution, censuring Sir Morell Mackenzie for publishing his work on the case of the late Emperor Frederick.

DR. VON LAUER, Physician-in-chief to the German Army and physician to the late Emperor William, celebrated, on December 18, 1888, his sixtieth year of service in the army. Congratulations were received from the Imperial family, the ministers, the faculties of all the medical colleges, the army medical staff, and many others. On December 14th a dinner and festival were given by the students of the Frederic-William Institute in honor of the occasion. Dr. von Lauer is now in his eightieth year.

WITH the new year the Sacramento *Medical Times* changes its name to the *Occidental Medical Times*.

REVIEWS.

THE EAR AND ITS DISEASES: BEING A PRACTICAL CONTRIBUTION TO THE STUDY OF OTOLOGY. By SAMUEL SEXTON, M.D., Aural Surgeon to the New York Eye and Ear Infirmary; Fellow of the American Otological Society, etc. Edited by CHRISTOPHER J. COLLES, M.D., Assistant Aural Surgeon to the New York Eye and Ear Infirmary. With Numerous Original Illustrations. 8vo. pp. 401. New York: Wm. Wood & Co., 1888.

THE author has not attempted to present to the profession a treatise on the ear embracing the entire field of otology. In the labor of collecting and condensing his clinical notes of more than ten thousand cases, the author has been ably helped by his assistants in the Infirmary, Drs. Wm. A. Bartlett, Robert Barclay, and Christopher J. Colles.

In studying the functions and diseases of the ear, the author has aimed to avoid a too exclusive consideration of local conditions in the ear, as he holds that otology "in its broadest sense should embrace a consideration of the upper air tract, of which the middle ear forms but a part, and of regions contiguous to the ear."

The term "chronic catarrh" as applied generally to certain morbid processes in the ear, is not always used by the author, in speaking of diseases usually called by that name, because he does not believe that in every instance this term is fully descriptive of the conditions present.

The following topics have received very justly prominent consideration, viz., catarrh of the upper air tract; oral irritation, especially dentition in its effects on the ear; sea-bathing as causative of ear disease; wounds and injuries of the ear; rupture of the drum-membrane from boxing the ears, and its medico-legal aspects; and concussion from explosions and the discharge of heavy artillery. We also find that amomalies of audition, noises in the head or ears, and their connection with the hallucinations of the insane, have received careful attention in this work, as well as the effects of false hearing in singers, actors, lecturers, and musicians. Othæmatoma occurring among lunatics, pugilists, and others has been presented very fully, and will be of interest to scientists and examiners in lunacy.

The operation of excision of the membrana tympani and ossicles, for otorrhæa and for deafness due to chronic catarrh of the middle ear, receives elaborate attention; and the results of the author's experience with this valuable operation are given. We are informed that these

results have been satisfactory, and it is hoped that its usefulness will be confirmed by the experience of others. We feel that this operation, mainly through Dr. Sexton's efforts, has already become a valuable addition to the means the aurist can command for relieving his patients.

Other subjects which have received due attention in this work are: the classification and education of school children with defective hearing; the effect of high atmospheric pressure on the ear in tunnels, caissons, and in diving; and the condition of soldiers, sailors, and marines seeking pensions on account of disability from deafness. Dr. Sexton has given to the profession a most interesting and valuable guide in the field of otology, which, from the perusal of this book, we are forced to conclude has become a wide one.

SOCIETY PROCEEDINGS.

THE GYNECOLOGICAL SOCIETY OF CHICAGO.

Stated Meeting, November 16, 1888.

THE PRESIDENT, CHARLES T. PARKES, M.D., IN THE CHAIR.

DR. A. REEVES JACKSON read a paper on

SOME UNCURED CASES OF UTERINE HEMORRHAGE.

CASE I.—Mrs. F. W. first consulted him July 7, 1884. She was twenty-eight years old, and had been married two and a half years; no pregnancy. Menstruation commenced at the age of sixteen, and had always been regular and in every way normal down to the time of marriage. After that event, a period occurred at proper time. The patient then missed two periods. After lifting a heavy weight, a flow of blood appeared and continued for several weeks. She visited Dr. Goodell, of Philadelphia, who curetted the uterus in May, 1883. He did not know what, or whether anything, was removed, but the patient considered herself well for four months. In the following autumn, two periods were again missed. After a trifling misstep a red flow began, and continued about one-half of the time for nine months; then he saw her. She was a large but not tall woman, weighing one hundred and sixty-two pounds, of dark and rather dull complexion, and habitually despondent temperament. There was no history or present evidences of disease of important thoracic or abdominal organs. The pelvic viscera were found to be entirely normal in size and position. The os uteri was rather small, but of virginal shape, and free from redness or erosion.

On July 9th he administered ether, and curetted the uterine cavity. A few fungous granulations were removed, and an application made of Churchill's iodine solution. This latter was repeated every four to seven days. For about three months menstruation appeared at intervals of four or five weeks, rather profusely, and lasting from seven to ten days. Then the interhemorrhagic periods became shorter—about three weeks. During the spring of 1885, the intervals were about two weeks; once, only nine days intervened. In the early part of 1886, the flow was more irregular, recurring every three to six weeks. In July, however, it appeared after an interval of two weeks, and lasted three weeks, not profusely but constantly. In August following, he again used the curette, without any result. Nothing was removed, and no change was produced in the symptoms. In June, 1887, the same operation was followed by a like negative result. A month later his connection with the case ceased.

During the time of his attendance (which was not continuous, but interrupted sometimes for periods of several months) the treatment consisted in efforts to overcome habitual constipation, and the intra-uterine application of iodine, carbolic acid, a solution of ferric alum, etc, These applications were always preceded by the introduction of a No. 12 bougie. There were two unfavorable conditions present in this case which he could not obviate. The one was tight-waist dressing, and the other an insuperable objection to active exercise. Within the past few days the husband of this patient called upon him and stated that the subsequent history of his wife presented no material change; that, at times, she seemed better, and then became worse again. She is now under the care of another physician, and is thought to be improving.

CASE II.—Mrs. E. D. placed herself under his care January 22, 1885. She had been married three years, and was never pregnant. Menstruation began at twelve, had never been distinctly regular, and for many years was rather scanty. During the past year, however, the discharge had recurred with greater frequency than ever before, the interval being less than four weeks, and it had become shorter and shorter, while, at the same time, the quantity of discharge at each period had steadily increased. During the month immediately preceding his first interview with the patient there had been three attacks of flowing.

This patient was of medium height, and much too stout to be termed plump. She had very dark and abundant hair, and there was a marked growth of hair upon her upper lip, on her face from the temporal regions to the chin, and on her neck. Interrogation failed to elicit any evidence whatever of cardiac, pulmonary, hepatic, or renal disorder. The patient ate well, slept well, and felt well. She was only annoyed by the frequency of the bloody flow. A pelvic examination revealed no abnormal condition, position, or shape of any of the organs. The single disordered symptoms discoverable consisted in a discharge of dark blood which was seen slowly oozing from the os uteri. The introduction of the sound was easily accomplished, and was followed by a rather profuse flow of redder blood.

Two days later, under ether anæsthesia, the cervical canal was moderately dilated, and the interior of the uterus curetted. A small number of fungosities were removed and the uterine cavity swabbed with Churchill's iodine solution. On February 20th, a bloody discharge appeared, and continued more or less profusely until March 14th—three weeks. He then made an application of Monsel's solution of iron. The discharge ceased for two days; it then reappeared and lasted to March 23d—seven days. He again dilated the cervical canal and passed in a curette, without removing anything, and applied the iodine solution. There was no discharge for eight days subsequently. Then a flow which seemed like that of menstruation appeared. It lasted five days, ceased two days, reappeared and continued with occasional intervals of one or two days until April 23d, when

it became profuse and seemed like menstruation again. After a few days the flow diminished, but a reddish-tinged oozing continued until a more profuse flow indicated the return of catamenial discharge. On November 9th, the patient reported that the longest time she had been free from bloody discharge was four days.

During all that time, he had availed himself of frequent opportunities of making local applications of iodine, carbolic acid, Monsel's solution, alum, fused nitrate of silver, etc. Also, he had given quinine, ergot, and viburnum, and on several occasions he had gently dilated the cervical canal, and tried to get away something with the dull curette.

No especial change was noticed in the symptoms in the summer of 1886, during which time all treatment was suspended. In January, 1887, the patient informed him that once only she was free from hemorrhage for a period of three weeks. Treatment was then resumed. He introduced a tupelo tent and followed the dilatation by a very thorough application of iodized phenol. This was repeated at intervals of five to seven days for several weeks. There was no improvement. Then, he tried nitrate of silver for a while, but the hemorrhage continued. In the summer of 1887, the patient went to Europe with her husband, and for a few weeks while there she was somewhat better. In the following autumn, however, after her return, the hemorrhage was as constant as before. On December 23d, he dilated the uterine canal mechanically under anæsthesia, and removed two large granulations. She died one week later of peritonitis.

CASE III.—Mrs. W. L., aged thirty-five years, had been married seven years, and had two children, the younger being sixteen months old. He saw her on September 5, 1885. When the baby was ten months old, menstruation appeared, and for two periods was quite normal, lasting four days. The third came a week too soon and lasted two weeks. After an interval of two weeks it again appeared, and when it had persisted ten days, necessitating two or more napkins daily, she applied for relief. She then showed effects of the loss in pallor, impaired strength, and enfeebled digestion. The baby was weaned, and the patient took strychnia, quinine, and arsenic. He found no pelvic cause for the hemorrhage unless it might have been a slight degree of subinvolution.

The uterus was freely movable, in normal position, free from erosion, and there was no swelling or undue tenderness in the region of the ovaries, tubes, or broad ligaments. Constipation was present, and he prescribed salines and a regulated nutritious diet. Subsequently, the hemorrhage continuing more or less constantly, although not profusely, other means were tried, many of them rather empirically. They included ergot, hydrastis, viburnum—all without perceptible effect. Then he dilated the cervical canal and explored the interior of the uterus with finger and curette. Nothing was found.

After about eight months, the patient placed herself under the care of an electrician, who treated her for nearly six months. Then she went to Cincinnati, and remained several months under the care of a distinguished gynecologist. She returned to him in January last, and stated that she had not at any time been more than ten days without a bloody discharge, and rarely more than three days. The menstrual periods were distinguishable by the more profuse flow which marked their presence, and they were fairly regular.

Once more he dilated the cervix under etherization, and drew a curette over every part of the intra-uterine surface, taking especial care to get the instrument into the cornual depressions. No tissue was brought away, and very little blood. He subsequently made internal applications of tinct. iodine, tannin, Monsel's solution, and once, at the close of what seemed to be a menstrual period, he applied nitric acid. While, at times, there was a diminution of the discharge, the improvement was only temporary, and in July last she again passed from his care.

CASE IV.—M. M., a single woman, aged twenty-five years, was born in Canada. Menstruation commenced at twelve, and was quite regular until she was nineteen; then the flow became prolonged, lasting sometimes five or six weeks. This was followed by irregularity, both in quantity and times of recurrence for a few months, when menorrhagia again appeared. At the age of twenty-two she was examined by a physician at Ottawa, who curetted the uterus, with what immediate result is not known, but the patient was free from all sanguineous discharge during a period of three months. Menstruation then returned and was regular, and in every respect normal for the following four months. Becoming menorrhagic again the curetting was repeated, with the same temporarily beneficial results as before. Again, after a few months, the flow became profuse, and a third curetting was made six months after the second, the latter time without apparent benefit.

The patient removed to Chicago, and came under the care of Dr. Stowell, with whom he saw her in the early part of the current year. On January 21st, after thorough dilatation of the uterine canal, he curetted very carefully, removing a small number of granulations. The operation was followed by the application of Churchill's iodine. For two months subsequently there was no bloody discharge. Then it reappeared, and Dr. Stowell has continued to treat the symptom in a routine manner locally and generally, but without satisfactory result. Latterly this case presents a curious feature: the flow is very profuse every alternate month, and normal the other.

Within the past fortnight this patient has been placed under the use of electricity, in the hope that she may be benefited by that remedy.

It will be observed that in the foregoing cases there were some features common to them all. Thus, in none of them did the hemorrhage take the form of rapid, profuse flow suddenly exhausting the patient, as we not infrequently notice in cases in which the discharge depends upon an abortion, or upon the presence of cancer or fibroid neoplasm. On the contrary, the evil effects produced were the result rather of the persistence of the discharge covering long periods of time. Again, in none of them was there evidence of disease of the lungs, heart, liver, kidneys, or other important organs causing a depraved condition of the blood or pelvic plethora. In none of them was there a history of hematocele, pelvic inflammation, or detectable pelvic swelling. In none of them was there any displacement or flexion of the uterus, or dislocation of the ovary. Indeed, in none of them could he determine a sufficient local or systemic cause. He had thought that possibly some such cause might

exist in disordered condition of the Fallopian tubes or pelvic cellular tissue not ascertainable by our present known methods of investigation.

Being aware of the influence of malarial poison in producing congestion of the abdominal and pelvic viscera, including perhaps the mucous membranes, he had not failed to take this possible etiological factor into consideration, and to make careful inquiry with the view of ascertaining its existence. The result in each case was wholly negative.

His object in reporting these cases was twofold: first, to ascertain whether others beside himself have met with similar baffling experiences; and, secondly, to obtain such practical hints in the treatment of such cases as may hereafter lessen the number in which we have to acknowledge defeat.

DR. D. T. NELSON thought that the only way we can arrive at a conclusion as to the nature of the disease, and, consequently, the proper method of treatment, is to follow them longer. One case that he had seen—and there is but one that seems to him at all like those reported—he was fortunate enough to see one or two years after a somewhat similar experience by other gentlemen, in which nothing was reported to have been found; in which there was curetting; but as he saw it subsequently there was plain evidence of fibroid tumor. Perhaps if these cases were seen longer or examined post mortem there would be a satisfactory explanation of the persistence of the hemorrhage. He thought that one of the small single or multiple fibroid tumors, which cannot be detected by the most skilful finger, or by any means of examination that we have at present, are likely to produce such results, and he believed that they may lie dormant for a longer period than these cases have been observed; he was quite sure that he had seen them—and eventually, perhaps of their own nature, develop so as to be found; perhaps from some exciting cause other than that.

There was another cause, he thought, for these hemorrhages, namely, disease of the Fallopian tubes. He did not mean by that a salpingitis that will fill the tube with pus or serum, and be so large as to be easily felt, but actual disease of the mucous membrane, perhaps not extending much deeper than the mucous membrane, but capable of producing a continuous hemorrhage. He was unable to point out a case in his experience, or in that of others, that is plain, but he simply threw it out as a hint, as a possible explanation, for further examination. Perhaps it is not a parallel case, and yet it seemed to him that there is a similar cause. A woman after menstruation, or a week after the cessation of the menstrual period, takes cold, has a slight cough, has a traumatism or some slight disturbance in the pelvis giving pain and other evidences of inflammation; we all know that one of the most common symptoms attending upon the pain, etc., is hemorrhage from the uterus. Not a severe one, perhaps, but a slight flow. It might be said, that means congestion of the whole pelvic viscera. True, it ordinarily does. But what does produce the uterine flow? Is it the uterus alone, is it the ovaries alone, is it the broad ligaments only, is it the Fallopian tubes and the uterus, is it the Fallopian tubes only? It seemed to him in some instances that it is only the uterus, not the broad ligaments and vascular structures about the uterus; but that the Fallopian tubes and ovaries have very much to do with this condition. He believed that if these cases were observed long enough, we should find a congestion of the uterus produced by a fibroma or sarcoma, or disease of the Fallopian tubes or ovaries, and preëxisting disease of the ovaries and tubes produces hyperæmia of the uterus that favors the development of fibroma and sarcoma.

DR. C. T. PARKES mentioned a report that he had recently read in one of the foreign journals that applied somewhat to this question. A case was reported where all these remedies were used; curetting and intra-uterine dilatation, and finally the surgeon concluded he would make an abdominal section. After making the section, he found what he reports as a cavernous angioma of one of the ovaries. It was removed and the case cured.

DR. A. REEVES JACKSON said that the cases which he had reported were not the only ones which he has failed to cure, but he had accurate notes of these, and he considered them sufficient for the purpose of bringing the matter before the Society.

The existence of fibroids, as a probable cause in some of these cases, as suggested by Dr. Nelson, had occurred to him. The question of possible pregnancy also arose, and he made such inquiries and investigations as he hoped would lead to a settlement of the latter point especially. We know that in fibroid growths of the uterus hemorrhage becomes by and by a prominent symptom, and usually it is the one which first calls the attention of the patient to her condition; and in these cases we usually have no trouble in the diagnosis where there is present either a polypus or a fibroid of sufficient size to alter the shape of the uterus or to be felt within the cavity of the organ. He could conceive how a very small fibroid, incapable of detection by ordinary methods and ordinarily skilled hands and fingers, might produce hemorrhage, but would it yield to the medical treatment of a fibroid? If it did not, we should hardly feel justified in making a laparotomy to discover the existence of a fibroid that presented no other evidence of its existence than hemorrhage. It is true that patients nowadays submit to laparotomy when they are urged to do so; yet the one who urges should have some kind of objective reason upon which to base his advice. In none of these cases could he detect any change whatever in the shape of the uterus. The fact is, that when we find a fibroid as the cause of hemorrhage, it is already surgical. It is large enough sometimes to have existed, with their slow rate of growth, for many years, and yet hemorrhage has probably not been present until the latest part of the history.

Disease of the Fallopian tubes, he had no doubt, is a frequent cause of persistent uterine hemorrhage. Primarily, the blood may have its source in the tube; later, by overaction—by the mere bleeding—there is produced manifest disease of the endometrium, as in the case last cited. But, granting this, inasmuch as we can only reach the uterine lining anyhow by our topical treatment, even if we have a suspicion that there may be tubal disease, it does not aid us in deciding what to do for it. The ethics of the condition are in doubt.

Allusion has been made to the death of the third patient. She died of peritonitis following the operation. He had reported it in order to call attention to the danger of what is usually considered a simple and safe operation. In this case, the operation was done under the strictest antiseptic precautions; every care was taken to avoid any danger from that source. Unfortunately, he was

obliged to leave the city shortly after the operation, leaving the patient in an unsatisfactory condition, temperature 102°, rapid pulse, red cheeks, and evident high constitutional excitement. On his return he found her still worse, and shortly afterward she died of peritonitis, whether septic or not he did not know. The dilatation was mechanical; it was not made by tents, which he considered a dangerous method of treatment.

He did not mention in the paper an important fact in the subsequent history of the last case. It was this: During the last examination he detected a distinct swelling at the side of the uterus, apparently in the Fallopian tube. Then he suggested that if the patient did not get better, here was a reason why we might properly make a laparotomy—not for the hemorrhage, but for the swelling which was possibly the cause of it. The curetting on three occasions certainly had a very satisfactory effect. On one occasion, for four months subsequent to the operation the patient had no bloody discharge whatever, natural or unnatural, which would seem to indicate that, at that time at least, the cause of the hemorrhage was in the uterus, and that the effect of the remedies applied more thoroughly after the dilatation had a controlling influence for a long time. This is very satisfactory to a patient who has been having a profuse or prolonged hemorrhage. This patient was under the care of excellent men in Canada, who, so far as he knew, never detected any swelling, and he inferred from this fact that the latter symptoms were of comparatively recent appearance.

The nitric acid, which he applied in one case, he formerly used a great deal more than he did now. His method of using it is that recommended by Athill some years ago. The uterus is previously dilated, and when sufficiently open, the pure nitric acid is passed into the uterine cavity on an ordinary cotton-wrapped applicator. He placed the patient on her back, introduced a perineal depressor, seized the anterior lip of the uterus, drew the organ down, and surrounded it entirely with cotton which has been dipped in a solution of bicarbonate of soda. The applicator is dipped into the acid, passed into the uterine cavity, and held there for a few minutes. It is then withdrawn and the vagina syringed until all fuming ceases. Then he removed the tampons from about the cervix, and another tampon saturated in glycerine is placed over the os uteri. Such was the method used in this case. The nitrate of silver he applied in this way: A few grains of the crystal are melted in the bottom of a test tube. A silver uterine probe is dipped into the fluid and withdrawn a few times, until a bead is formed on the end of the instrument the size of a grain of rice. This is passed through a speculum up into the interior of the uterus, and held there for a few minutes, and slowly drawn out so as to come in contact with the surrounding membrane. This method has been recommended as very effective in chronic cases of menorrhagia. The hydrastis he has used a good deal. Loewenthal has reported several cases in which he has used hydrastis for preventing menstruation absolutely in persons to whom it was injurious; chlorotic and anæmic patients, he affirms, have been effectually cured by the use of hydrastis, given so as to obliterate absolutely the function of menstruation. He has never used it for this purpose, but he believes in the principle. He did not believe menstruation, of itself, does any woman any good.

As to the relative frequency of inflammation before and after the advent of antiseptics, he was hardly prepared to answer. If the theory of septic inflammation is correct, all diseases resulting from the ordinary operations ought to be less, if antiseptic precautions are used. He remembered but three cases of ordinary operations in which death followed. Inflammation was present in all of them, and it may have been of a septic character, and so may it have been in this last case which he related. But the patient complained of pain immediately after the operation, and she was never free from pain until the time of her death, six days later.

Ergot he has not found to be beneficial in any condition of the uterus involving hemorrhage, unless it be subinvolution during its soft stage where the uterus is large and heavy. In those cases he believes ergot is an excellent remedy. That condition was not present in any of these cases. Whether in one of them the cessation of menstruation for two months indicated pregnancy, he did not know, but there was no other evidence of it; there was no fœtus observed; nor was the history that of an early abortion, so that the single symptom of absent menstruation in a woman who was irregular at times was not so significant as it might be under other circumstances.

In the case stated by Dr. Parkes, the disease of the ovary was found, as he understood, after all other theories and much treatment had been exhausted, and it was supposed that there *might* be some disease *somewhere* in the pelvis which could only be detected and possibly removed by laparotomy. But it is doubtful whether this would be a safe rule to follow even when all technical means and all known remedies for persistent hemorrhage have failed; if the woman is not endangered by the hemorrhage would it be right to subject her to any risk of her life for a *possible* cure? If life were jeopardized, there could, of course, be no question as to the propriety of laparotomy. This, however, was not the condition in any of the cases which he had related.

DR. EDWARD B. WESTON read a paper on

A NEW PROCEDURE IN CASES OF ANTICIPATED COMPLETE RUPTURE OF THE PERINEUM.

On the 4th day of October he was, for the fourth time, called to attend Mrs. H. in labor. She is a woman somewhat below the average size, and has rather a narrow pelvis, while her children are all large at birth. At the birth of her first child, a boy who weighed twelve pounds, she received a complete laceration of the perineum. The second child, also a boy, weighed nine and a half pounds, and the perineum was torn to the anal sphincter. The third pregnancy was terminated in the sixth month by unknown cause. The child was, of course, small, but delivery took place very rapidly, and there was again a rupture, though not to the same degree as in the second labor. On visiting the patient at the beginning of her last labor, an examination showed a well-restored perineum, and a child seemingly very large presenting in the first position.

Meditating over the situation, remembering what had taken place in her previous labors, he feared a complete rupture would again occur, however well he might apply the various methods or procedures for protecting the perineum. The thought came to him that it would be well to introduce a deep suture before the laceration occurred, and before the head began to press upon the

perineum, so that if complete rupture did take place he should have one suture already in place, by means of which he could easily bring the parts into accurate apposition, and which could in a measure be used as forceps or tenaculum, and be of great service in whatever after-operation might be necessary. He could see no objection to the step; so with a long curved needle he introduced a silk suture a little more than half an inch to the right of the anus, and carried it up about an inch and a half in the recto-vaginal septum, and brought it out on the left side at a point corresponding to its point of entrance. He left either end six inches long and tied them together. Again there was a laceration, though not a complete one. The child, a boy, weighed eleven pounds.

He then considered the objection which would be raised to the procedure. One objection will be that we cannot tell when we are to have a complete rupture. We cannot always know in advance, and here the unexpected often happens. But in some cases we feel very sure it will occur, and it is in these cases that the stitch should be introduced. And in cases of doubt the stitch had better be placed, as it will in any event do no harm. Another objection may be that, if rupture should take place, we cannot tell what direction it will take. In the great majority of cases, externally, the laceration occurs, practically, in the median line. So that whatever its internal course may be, all the advantages claimed for the stitch will be obtained. Again, that should the procedure be recognized as proper in certain rare cases, it will be abused by too frequent use. And that, with the stitch in place and with confidence in the future assistance to be derived from it, our vigilance in protecting the perineum might be relaxed. To these objections he could only say that the conscientious accoucheur would not be influenced by them.

Some will suggest the danger of sepsis. He did not believe this need be feared. If antiseptic precautions have been observed, and the stitch buried in the tissues through its whole length, the increased danger will be nil. If, fortunately, rupture does not occur, the stitch can be cut short at one side, withdrawn, and no injury will have been done. Others will say that, even should complete rupture take place, the physician should be skilful enough to repair it by some one of the old methods. This is true; but the fact remains that there are all degrees of surgical skill, ranging from no skill to that of the highest degree. It may also be said that the obstetrician who would introduce the stitch before laceration occurred would be the very one who would have least need of it afterward. He granted this. But the majority would prefer to have the stitch in place, rather than to begin repairs without it, the parts being not only lacerated, but often so contused, swollen, or retracted that their normal relations can scarcely be made out.

If, by the procedure suggested, some one may be enabled to repair a complete laceration of the perineum, which otherwise would be left for a gynecologist to repair after the patient had suffered, mentally as well as physically, for weeks or months, he thought it should be objected to. And however expert an operator may be, it is true that the easiest, simplest way of obtaining a desired result from operative procedure is the best way.

These were the chief objections which have occurred to him as likely to be raised. The advantages of the procedure have already been sufficiently indicated.

DR. H. P. NEWMAN suggested as a substitute for this manner of procedure one that has been long in use, namely, episiotomy, or bilateral incision of the vulva. It has served him well in one or two instances. It has this obvious advantage, that it allows of tearing laterally in such a way as not to injure the perineal muscles, or weaken the recto-vaginal wall. In this way he can also prevent complete laceration, where some tearing is inevitable. He should regard Dr. Weston's method as a most admirable means of placing the initiatory stitch, where rupture seems imminent, although he could not see how it could well obviate the tear.

DR. E. W. SAWYER desired to say in connection with making the slight lateral incision, or episiotomy, that it does often prevent the laceration from occurring in the median line. He has made these incisions, one on either side, in nearly every forceps case in primiparæ, and he never saw the least harm come from it. In some instances, when he thought the perineum would be extensively torn, the laceration was really very short and insignificant. He thought the suggestion of Dr. Weston is most excellent; it is in exemplification of the old axiom that a stitch in time saves nine, and he having attempted to repair an entirely lacerated perineum more than once immediately after parturition, knew something of the difficulty of introducing a deep, properly applied suture, and if he could have the first suture introduced when the parts were in their normal relations, he should consider that he had overcome the greatest obstacle in immediate repair. He did not see one objection to the introduction of the suture.

DR. JACKSON thought that the suggestion made by Dr. Newman was not a very new one. The two incisions should not be lateral but diagonal, so as to pass about one-half inch on either side of the fourchette directly outward, going beyond the rectum on either side. He had never used it, but it seemed to him that in a case where complete laceration seemed inevitable it would certainly be a preferable procedure to allowing the perineum to rupture. He did not understand Dr. Weston to say that the stitch recommended by him would prevent the laceration, but that it would aid in its repair, and from this point of view he regarded the suggestion as a very valuable one. It would certainly simplify the primary operation for rupture of the perineum.

DR. E. B. WESTON said that this stitch was not suggested as a preventive, but simply as an aid, in case a laceration should take place after all we had done, whether by episiotomy or any other method which we could think of, in bringing the parts together.

CORRESPONDENCE.

THE HEALTH OF ST. AUGUSTINE.

To the Editor of THE MEDICAL NEWS,

SIR: Rumor of prevailing sickness in St. Augustine makes the following statement of interest.

Continued effort toward sanitary improvement since the outbreak of epidemic yellow fever in Key West, in the spring of 1887, increased by the nearer approach during the past summer, has shown definite results, not only in external appearances, but in a reduction of death-rate and absence of disease dependent upon vitiated air.

From August 11, 1888, until the frost of December

20th (temperature 29°, official), this city was guarded by a cordon of 210 men by land, and 25 by water approach, under discipline of military strictness. In September dengue fever made its appearance. Its return in this month, or in October, is common, and excited no concern. Absent physicians were instructed by the Board of Health that their services were not required. Dengue is regarded with no more gravity than a common cold at the North; few called their physicians, and all recovered within the usual two or three days.

The fact that no death occurred from dengue fever, and that the disease disappeared spontaneously before the middle of October, sufficiently disproves any opinion that this may have been the dreaded enemy. There has not been a case of fever of any kind in November or December, to my knowledge, and I am not aware of one at the present time. Among the officers and troops, and their families, the records indicate no sickness. The city register of deaths shows the number to have been, in August, 13; September, 10; October, 9; November, 10; December, 11; January, to date, 1; only 5 out of the 54 being the result of climatic causes, viz., 2 typho-malaria, 1 dysentery, 1 diarrhœa, and 1 continued fever.

Very respectfully yours,

FRANK F. SMITH, M.D.

ST. AUGUSTINE, FLORIDA, January 8, 1889.

NEWS ITEMS.

The Prevention of Puerperal Fever.—For the purpose of preventing puerperal fever, as well as other infectious diseases of childbed, the following rules, to be added to those found in the *Manual of Midwifery for Prussian Midwives*, have just been promulgated by the Minister of Education, under date of November 22, 1888.

1. The midwife must pay the greatest attention to cleanliness; this cleanliness is to be especially observed during delivery and in attending the mother in childbed.

2. While attending to her duties the midwife is only to wear dresses the sleeves of which will admit of being rolled up to the arm. The dress itself must be covered with a broad, white apron, covering the bosom, and made from a light, and washable material.

The apron which has been worn by the midwife during her first examination of a woman in labor, or while attending to a woman in childbed, is not to be used immediately after the last washing, but is to be separated and laid aside from the rest of the midwife's wearing apparel.

3. Before going to a confinement, or to a woman in childbed, the midwife will see that her finger-nails are cut short and round, and the edges are smooth; she must remove the dirt from her nails, and ungual folds as well as from any possible cutaneous fissures of her hands, and wash her hands and forearms thoroughly, for which process she is to use her own soap and hand- and nail-brush.

4. Besides the articles mentioned in § 96, abstr. 1 of the *Manual of Midwifery*, a midwife will carry the following articles:

a. A clean apron of a light, washable material (one which has not been used since last washed), which must cover the entire front of her dress.

b. Soap to clean hands and arms.

c. A clean nail- and hand-brush (her own property) for the same purpose.

d. A clean towel, which has not been used since it was last washed.

e. Three ounces of pure carbolic acid in fluid form, in a bottle, bearing the following inscription in clear type: *Caution! Carbolic acid! Dilute thoroughly; for external application only.*

An accompanying irrigator to hold two pints, to have the pint marks plainly visible, and to be supplied with a well-fitting rubber tubing, from one to one and a half yards long. The bottom of the irrigator to be flat, and it, as well as the necessary connecting tubes, to be made of glass.

5. The midwife is responsible for the cleanliness of her utensils, and for the safe-keeping of the carbolic acid, which latter must be inaccessible to any other person.

6. Vaginal examinations of a pregnant woman, or of a woman in labor or in childbed, must never be undertaken by a midwife unless with bare and thoroughly clean hands and forearms.

Before making an examination by which she comes in contact with the genitals of the woman examined, or with a possible wound in the region of these parts, the midwife must roll her sleeves up to her arm, and fasten them in such a manner that they cannot unroll, then thoroughly wash her hands and forearms in lukewarm water, using for this purpose her own soap, nail- and hand-brush, and dry her arms on a clean towel, which has previously not been used. The same mode of procedure holds good when examining the external genital organs or any adjacent parts, for the drying of which she is to use absorbent cotton or jute, but never a sponge.

Besides this, it shall be the duty of the midwife to see that in cases of confinement, circumstances permitting, the mother is supplied with clean linen, which has previously been warmed, as well as clean bed-linen during the period of confinement and throughout her childbed.

After these preliminaries the midwife is to thoroughly disinfect her hands and forearms with the carbolic acid solution, after which she may proceed to examine the pregnant woman, woman in labor, or in childbed.

7. Where the words "carbolic acid solution" are mentioned, reference is had to a solution which the midwife is to prepare in the following manner:

To every two pints of water she shall add one ounce of carbolic acid, and in such a manner that the acid, which is somewhat heavier than water, does not settle to the bottom of the dish, but is equally distributed. This is best attained by pouring the solution into a bottle and thoroughly shaking the same. If the mixture is prepared in an ordinary round dish, the acid is only to be added by degrees, stirring constantly while so doing. The acid is *never* to be directly poured into the irrigator, because the acid not being thoroughly diluted, might sink to the bottom of the receptacle, and when drawn off injure the part it is applied to, most severely.

8. Before the first examination of a woman in labor, the midwife is to prepare four pints of the carbolic acid solution. Of this she shall put so much into the irrigator, that the tubings, catheter, and umbilical scissors, which she has previouly laid therein, are entirely covered with the solution. If one of the instruments is utilized, it must, after having been used, be thoroughly washed with soap, dried, and be put back into the irrigator, and kept there until no longer needed. If the irrigator is to be used for injections or washing purposes, it will be necessary to put

the instruments and the carbolic acid solution into some other vessel.

The remainder of the solution—about three pints—is to be divided into two equal parts, and put into two vessels. One of these is to serve for the *first* disinfection of the hands and forearms of the midwife, the other for any subsequent cleansing of her arms and forearms after each and every examination of the mother, or any other doings which would bring her in contact with the generative organs, or with any wound adjacent to the same.

9. After labor, it shall be the duty of the midwife to wash the external genital organs with clean, lukewarm water (which has been thoroughly boiled), and to dry the same with a clean towel or absorbent cotton.

10. The midwife shall not wash out the vagina or give the mother any injections without a physician's permission, except in such cases as are mentioned in the *Manual* when she is to use the carbolic acid solution instead of water.

11. The midwife must avoid any unnecessary contact with the genitals of the lying-in woman, or with parts soiled with the lochia, or with any bad-smelling or purulent portion of the body (as ulcers, a dead fœtus, linen soiled with the lochia, etc.), and must avoid as much as possible all intercourse with persons suffering from any contagious disease, or any suspicious illness, as childbed-septicæmia, metritis, perimetritis, diphtheria, scarlet fever, smallpox, syphilis, chancre, gonorrhœa, typhoid and typhus fever, cholera, or dysentery.

12. Should the hands or instruments of the midwife have come in contact with the genitals of a lying-in woman, or with any article soiled with the lochia, she shall immediately cleanse her hands with soap, nail- and hand-brush, while her instruments must be cleansed and placed in the disinfecting solution for one hour, as before labor.

13. Should the lochia have a bad odor, or be purulent, or the midwife have come in contact with any article which has been in contact with these discharges, or should the person with whom the midwife has come in contact with her hands and instruments, be suffering from any of the diseases mentioned in § 11, the midwife shall follow out the rule laid down in § 12, and cleanse her hands and forearms for at least five minutes in the carbolic acid solution, and boil her instruments for one hour in water before placing them in the carbolic acid solution.

14. Should the midwife have been to the dwelling of a person suffering from any of the following diseases, or from any suspicious disease, as childbed-septicæmia, metritis, perimetritis, erysipelas, diphtheria, scarlet fever, smallpox, syphilis, chancre, gonorrhœa, typhoid and typhus fever, or dysentery, she must not examine a pregnant or lying-in woman, nor even call on her, before she has changed her wearing apparel, and has cleansed and disinfected herself as prescribed in § 13.

15. Should a person suffering from any of the diseases mentioned in § 14 live in the same dwelling with the midwife, or should a lying-in woman under the midwife's care have died of puerperal fever, metritis, or perimetritis, or be suffering, or have died from a suspicious illness, the midwife shall obtain all further orders from the district physician, and shall, until such are forthcoming, abstain from any further prosecution of her calling.

16. Should the midwife be nursing a lying-in woman suffering from puerperal fever, metritis, or perimetritis, or any other suspicious illness, she must not under any circumstances examine a pregnant woman; and a woman in labor, or a lying-in woman, only when another midwife is not to be had, and under such circumstances only after having bathed and cleansed her entire body in water and soap, and then disinfected and dressed herself in clean clothes, as laid down in § 14.

17. The wearing apparel which the midwife has worn at the examination of a person infected with any of the diseases mentioned in § 14, must not be brought in contact with her other wearing apparel, but must be thoroughly boiled, washed with soap, and disinfected with steam in a steam-disinfecting apparatus before being again used.

18. The midwife must never touch a corpse, or the clothing worn by a corpse. Should she, however, have done so, she must proceed as laid down in § 16.

Medical Royalties.—According to *Truth*, "Prince Louis Ferdinand, of Bavaria, who is married to the Infanta Paz, is a very clever surgeon, and at one of the hospitals in Madrid he recently operated on a woman who was suffering from cancer of the breast, with complete success. His relative, the Duke Charles Theodore, brother of the Empress of Austria, is both oculist and surgeon, and is very skilful; but his fondness for the knife is not appreciated at the Vienna and Munich hospitals, for whenever he operates all the regular arrangements are upset, the whole staff is required to be in attendance on him; he must always be respectfully addressed as "Your Royal Highness," and strict etiquette is observed, all of which is decidedly a nuisance. When the Duke is at Vienna, he often passes the whole day in the General Hospital, and if there are any arms or legs to be cut off, he hastens joyfully to the work. Duke Charles's zeal may possibly be moderated by his accession to the Bavarian estates of his father, Duke Max, who died the other day. He is married to a cousin of the King of Portugal."

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 8 TO JANUARY 14, 1889.

By direction of the President, ROBERT W. SHUFELDT, *Captain and Assistant Surgeon*, will report in person to Brigadier-General Wesley Merritt, President of the Army Retiring Board, at Fort Leavenworth, Kansas, for examination by the Board.—Par. 1, *S. O. 4, A. G. O., Washington*, January 5, 1889.

By direction of the Secretary of War, R. W. JOHNSON, *Captain and Assistant Surgeon*, is relieved from duty at the U. S. Military Academy, West Point, New York, and will report to the commanding officer, San Carlos, Arizona, for duty at that post.—Par. 10, *S. O. 7, A. G. O., Washington*, January 9, 1889.

JOHNSON, RICHARD W., *Captain and Assistant Surgeon* (U. S. Army).—Is granted leave of absence for fourteen days.—Par. 1, *S. O. 8, A. G. O., Washington*, January 10, 1889.

By direction of the Secretary of War, JAMES E. PILCHER, *Captain and Assistant Surgeon*, will repair from Fort Wood, New York Harbor, to Philadelphia, Pa., at such time as his services can be spared, for the purpose of giving instruction to the Hospital Corps of the First Brigade, National Guard of Pennsylvania.—Par. 6, *S. O. 8, A. G. O., Washington*, January 10. 1889.

HARRIS, HENRY S. T., *First Lieutenant and Assistant Surgeon* (U. S. Army).—Will, upon the arrival of Acting Assistant Surgeon Boyer, proceed from Camp Pena Colorado to the post of San Antonio, Texas, and report to the commanding officer, for temporary duty.—Par. 4, *S. O. 1, Headquarters Department of Texas, San Antonio, Texas*, January 2, 1889.

POISONING BY CHROME YELLOW USED AS A CAKE DYE.

The Subsequent Clinical History of the Cases, Including a Case of Paralysis Agitans and of Chronic Endocarditis.[1]

BY DAVID DENISON STEWART, M.D.,

CHIEF OF THE MEDICAL CLINIC OF THE JEFFERSON MEDICAL COLLEGE; PHYSICIAN TO ST. CHRISTOPHER'S HOSPITAL FOR CHILDREN.

I REPORTED, in September, 1887, a clinical analysis[2] of 64 cases[3] of poisoning by chrome yellow used as a cake dye. The present paper is a further history of such of these as I have had under observation to the present, a period of fifteen months.

8 of the 64 died in convulsions. The later history of 12 of the 56 survivors I have been unable to ascertain. Absolutely nothing could be learned of 6 of the 12; they are, however, believed to be living. I regret I am unable to report their condition. They were severely poisoned, after prolonged exposure. Nor could sufficient be learned of the second 6 to justify their consideration here. Several of these were personally questioned but with unsatisfactory results.

At the time the data for the analysis of the 64 cases were being collected, all of the 44 now reconsidered exhibited some unmistakable and pronounced symptoms of plumbism, such as cachexia, colic, arthralgia, or encephalopathy, and the blue line was present in the gums of all save 1. A minority only of the 44 received any continuous treatment, and many of these were in the hands of homœopathists, who, it is believed, did not give eliminants. The health of 31 of the 44 is yet decidedly impaired, and several of the remaining 13 ail slightly.

The lead cachexia is still present markedly in 12. In these the skin has been of a decided earthy-yellow hue, continuously since the poisoning. The gums of 8 of the 12 show a fading though distinct blue line, and are retracted from the teeth. In 3 of the 12 there is a purplish line, and in 1 no trace of a line exists. Considerable anæmia[1] is present in those in which cachexia is yet marked, and in 1 in which cachexia is absent. The mucous membranes and conjunctivæ are pale. In several a venous hum can be heard in the neck; and, in 1, a basic (pulmonary) murmur.[2] Most of the 12 have breathlessness and palpitation on slight exertion. Several speak of præcordial pain. 8 of the 12 are very dyspeptic; 5 have yet occasional attacks of severe colic which occur unprovoked by food or other known cause. All of the 12 have headache, which in several is severe and constant.

Evidences of functional derangement and of organic disease of the heart have appeared in 7 of the 44 since the poisoning. In 6 of the 7 there are present symptoms of cardiac irritability, such as præcordial pain, increased by exertion and then accompanied by palpitation and shortness of breath. In 2 of these the palpitation and shortness of breath occur often when at rest and in recumbency, as at night. All of the 6 have increased frequency of pulse, and the heart of each is overacting, with accentuation of the second sound at the apex and some increase in the area and force of the impulse. In 3 of the 6 this increase is greater than can be accounted for by mere functional overaction, and other accompanying physical signs and symptoms indicate slight but unmistakable hypertrophy. The seventh case illustrates one of the insidious effects of chronic lead poisoning, a tendency toward slow degenerative changes in the vascular system. There was at first irritable heart, which was succeeded by hypertrophy, and that by a chronic mitral valvulitis with insufficiency. Dilated hypertrophy of the left ventricle then followed.[3]

---

[2] This paper was published in THE MEDICAL NEWS, December 31, 1887.

[3] In addition to these, I have notes of 15 others, making a total of 79 undoubted cases traced to 2 bakers. The 15 include 4 cases of lead convulsions, which in 3 ended fatally. It is unfortunate that I was unable to obtain the histories of very few of the large number of early patrons of Palmer, the baker, who used the dye freely for years in another section of the city than that in which he was apprehended. No doubt there were many interesting cases of plumbism among these.

It is to the point, in this connection, to state that I believe I can trace to lead-poisoning from dyed cakes many cases of disease of seemingly obscure or supposed idiopathic origin, seen in the past year and a half of my service in the out-patient medical department of the Jefferson College Hospital. Among these are cases of pronounced anæmia, renal fibrosis, peripheral neuritis, spastic paralysis, neurasthenia, obstinate headache, and, at least, one case of long-standing delusional mania.

[1] Through an utter lack of coöperation and interest on the part of these cases, none of which were my patients, I was unable to obtain a blood examination.

[2] This was not examined for in all.

[3] Professor Da Costa, to whom I showed this case somewhat more than a year ago, when the valve changes were not perceptible, and, later, when they were markedly present, fully agrees with me as to the pathological condition, and as to its plumbic origin.

The case is that of Mrs. H. H., aged forty-seven. There is absolutely no history of rheumatism, gout, syphilis, or alcoholism. Her health had always been good until the spring or summer of 1886. Attacks of typical lead colic then developed with the usual attending phenomena. These continued, at intervals, until the summer of 1887. There were also present during this period severe headache and constant mental and physical exhaustion. Slight pains in the ankles, unaccompanied by any inflammatory condition, but with sensations of numbness and burning in the soles of the feet, were occasionally felt. When first seen in June, 1887, she had been a patron of Palmer for fifteen months, and had eaten almost daily of the dyed cakes. Her condition then was much as has been stated. In addition, it was noted that she was emaciated and dyspeptic, had palpitation and shortness of breath on exertion, and præcordial pain. There was heightened arterial tension, a much overacting, irritable heart, but no murmur. Lead was found in her urine by Dr. Leffmann at this time, and an examination of the eye-ground by Dr. Hansell showed "œdema of both retinæ, with effusion into the right retina below the fovea; pulsation of larger and tortuosity of both large and small veins."

Because of her absence from the city during the summer of 1887 I saw her but seldom. Ailing severely in September following, she presented herself for regular treatment, and has been under constant observation to the present. The mental and physical prostration had persisted, and, in August, coarse tremor, involving the head and limbs, had appeared. The shaking began each morning on rising, and continued constantly through the day. It was especially aggravated by physical exertion. Decided weakness of grasp accompanied it, but no paralysis. She had continuous headache, and palpitation was so troublesome at night that she was unable to rest in recumbency. Early in September there was found extreme overaction of the heart, with undoubted hypertrophy of the left ventricle. No murmur, however, could be detected until about the 14th of October following. There had then developed a faint systolic mitral bruit, which was accompanied by distinct accentuation of the pulmonary second sound. Palpitation was now more distressing than formerly, and was associated with attacks of shortness of breath and of dyspnœa by day, but oftener by night. Prior to this, believing renal fibrosis was in progress, the urine, which had been of a low gravity and profuse in amount, had been frequently examined for albumin and casts, but always with negative results. Shortly subsequent to the development of the murmur albumin appeared, detectable at first only with picric acid, but soon with nitric. The amount never exceeded a gramme to the litre, and was usually less. Coincident with the appearance of the albumin the urine diminished in quantity, and hyaline and granular casts were very often found, sometimes in large amount.

The remaining facts in the case are concisely as follows: The mitral murmur became louder, and the area over which it could be heard greater. Evidences of stretching of the left ventricle soon appeared, and, with these, signs of overloading of the pulmonary and general venous circulation assumed prominence. The attacks of dyspnœa at night deepened into orthopnœa. There were cough and frequent blood-spitting. The ankles and feet were at first puffy, and then swollen. Purpuric spots appeared on the legs. The portal circle was constantly congested, causing an icteroid hue of skin and pronounced gastro-intestinal catarrh.

This condition of things continued pretty constantly until the spring of 1888. She then improved very steadily, and the more pronounced signs of "back-working" were only occasionally present. Since April last the daily quantity of urine passed has been normal or above, and albumin and casts have been absent. All the usual symptoms of plumbism had disappeared at this time, The tremor persisted intermittently for months, but grew less and less frequent as her condition ameliorated.

The physical signs referable to the heart are now those of mitral regurgitation and dilated hypertrophy of the left ventricle, with hypertrophy in excess of the dilatation. The murmur is very distinct, and has the usual characteristics of that of mitral insufficiency. Though there are yet almost constantly present some indications of mechanical derangement of the circulation, such as œdema of the ankles and legs, congestion of the portal viscera, and, at times, of the lungs with blood-streaked sputum or actual bloodspitting, and attacks of bronchial catarrh, freedom from excessive palpitation in the past few months could be obtained only by the persistent use of aconite. Digitalis and strophanthus, which, in moderate doses, were of service a year ago, now aggravate the palpitation, and do not materially lessen the tendency toward venous congestion. The attacks of dyspnœa, which occur once or twice weekly, are relieved, as before, by free dry cupping of the chest. Restorative agents, such as arsenic, iron, and the vegetable tonics, are employed to improve nutrition. Frequent resort to purgatives is necessary to relieve the portal stasis.

I have no doubt that some cases of chronic endocarditis, the origin of which we are at a loss to account satisfactorily, a history of acute articular rheumatism or of strain not being obtainable, are of lead origin.[1] Lead is, I believe, a more frequent

[1] Chronic valvulitis, as a result of lead poisoning, is not uncommon. Duroziez reported (L'Union Médicale, December 15, 1885) eleven cases of mitral stenosis and one of aortic regurgitation, occurring in plumbic subjects in whom there was absolutely no other assignable cause for the valve affection.

A typical case of lead endocarditis, originating aortic stenosis and mitral regurgitation, is that of B. F. K., a painter for twenty-eight years, who has been under constant observation in the out-patient medical department of the Jefferson College Hospital since 1881. He first presented himself for treatment because of obstinate colic and an ileocolitis which had arisen in consequence of lead-poisoning. There was a well-marked blue line, typical lead cachexia, constant headache and vertigo, and distressing arthro- and generalized neuralgia with cramps in the muscles of the extremities, and jerking of the limbs. The urine was free from albumin. His heart was examined on several occasions by Prof. Da Costa between 1881 and 1885. On the first exploration there were found considerable overaction, and a soft

cause of chronic endocardial inflammation than gout, syphilis, or alcoholism. Even where a doubtful history of rheumatism exists, we should not be deterred from an inspection of the gums and an inquiry as to the possibility of lead poisoning in the past. In all cases of valvulitis of seemingly obscure source this should be done as a matter of routine. A caution is necessary that a mere history of pains in and about the joints must not be accepted as undoubted evidence of rheumatism, without a careful investigation as to signs of accompanying arthritic inflammation; for it is undoubtedly a fact, of which I have seen striking examples, and the non-recognition of which by practitioners has caused many lead cases to be overlooked, that arthralgic pains are among the most common of the protean manifestations of plumbism; and that they may persist for lengthy periods entirely without other noticeable symptoms, save, perhaps, cachexia; and that even the latter may be absent in undoubted cases.

An abnormally forcible cardiac impulse, with accentuation of the aortic second sound and increased tension in the peripheral arteries, is constantly present in many cases of lead cachexia. In these a tendency toward insidious valvular changes must be great, and this is no doubt favored by the state of faulty nutrition and anæmia always existing in such cases. Simple anæmia is supposed sometimes to originate chronic valvulitis, through the augmented arterial tension present in its earlier stages causing increased backward stress on the valve curtains, and especially on the mitral leaflets, which, with each ventricular systole, are subject to a force equalling the resistance of the whole arterial circuit. Since the conditions favorable for the production of chronic valvulitis are more constant and decided in plumbism than in ordinary anæmia, it is not unlikely that chronic lead poisoning is oftener a cause of slow valve changes than mere poverty of blood. Having in mind the wide prevalence of lead poisoning and the frequency in the past year and a half with which I have encountered cases of somewhat obscure type, which no doubt I would have previously overlooked, because not on the watch for them, and seeing repeatedly in my service in the out-patient medical department of the Jefferson College Hospital cases which have passed through the hands of other practitioners unrecognized, I believe it probable that mitral stenosis, often met with as an insidious affection in young anæmic women free from rheumatic history, not infrequently owes its origin to unsuspected lead poisoning.

Disorders of digestion are prominent in a number of the 44, independent of colic or colicky pains. One (Mrs. G. A.), who was so prostrated by long-continued colic and arthralgia, that she was confined to bed for two months, and lost thirty pounds in flesh, has, in addition to attacks of severe generalized headache, constant gastric irritability. A trifling dietetic error which in health would not affect her, now readily provokes vomiting.

Obstinate constipation is yet present in 7. In these the bowels do not move without purgatives.

A chronic catarrhal enteritis has existed in 1 since his first attack of colic fifteen months ago. There are five or six loose passages for three or four days, succeeded by two or three days of constipation. Abdominal tenderness and pain are felt, in addition to colic which is yet frequently present though in a milder form. He had arthralgia affecting the knees and ankles for months, so severe that he was compelled constantly to maintain the recumbent posture. He also had wrist-drop.

Apart from slight colicky pains, which have been frequent in many since the abatement of pronounced symptoms of plumbism, and which, in a few, may be traced to dietetic errors, paroxysms of abdominal cramp having all the intensity and character of true lead colic, yet occur in 5. The seizures appear at longer intervals, as time passes, and are lessening in intensity. At first the interlapse averaged from ten to fourteen days, and the duration of the attack was three to seven days, but the former gradually lengthened and the latter diminished, until recently, in each of the 5, a severe seizure occurred about every four to eight weeks, and lasted from one to three days. None of these cases received regular treatment. In all there is reason to believe lead is yet present in the system.

Pains about the joints and in the muscles in their vicinity yet occur in 15.[1] In some the pains have been constant, with exacerbations and remissions; in others they have occurred intermittently every five to thirty days, in attacks lasting three to ten days. The ankles and knees, and the neighboring muscles are most frequently affected in 9; 3 of these have in addition sharp stabbing pains in the wrists, and 1 of the latter, pain in the hip. In 2 others the ankles, knees, and hips are equally affected; in 1 solely the ankles and wrists, and in another the lumbar and sacral regions. Dull and aching, burning or darting pains in the muscles

systolic murmur limited to the apex. In the autumn of 1884 the area of cardiac dulness was found to have considerably increased. The apical murmur was very distinct, rather harsh in quality, and was well transmitted toward the inferior angle of the left scapula. There was now present a systolic right basic murmur, distinct in quality and pitch from the apical bruit, and heard in the carotid artery. There had been frequent cardiac pain, attacks of palpitation, and signs of arterial ischæmia. At the present writing the mitral and aortic murmurs are very distinct. Compensation is good.

[1] 13 of these received no treatment, save from homœopathists; the remaining 2 were under a regular physician's care for two or three weeks when first affected.

adjacent to the affected joints accompany the arthralgia in all, and these muscles are yet the seat of frequent painful cramps. 2 have, beside the joint pain, very sharp darting pains in the forearms and wrists, in the course of the nerve trunks, associated with some loss of power and weakness of grasp. In 2 others[1] severe burning in the soles of the feet, alternating with numbness and tingling in the feet and hands, is sometimes felt simultaneously with the arthralgia.

Very painful and persistent inframaxillary neuralgia is present in 2 of the 15. Neither has carious teeth, and each has had several sound teeth extracted without the pain ameliorating. Aching in the right clavicle frequently accompanies the arthralgia in 1. General muscular aching and loin pains persist in 3. It is believed that inflammatory conditions of the joints, such as redness, heat, or swelling, at no time occurred in these cases. They were frequently searched for. The pains in nearly all are aggravated by night. Damp and cold weather increase them in 5.

I was recently able to ascertain the state of cutaneous sensibility in 8. Some anæsthesia was present in the area supplied by the peroneal nerve and its terminal branches in 2; there was plantar anæsthesia in 2 others; in 4, sensation was normal or hyperæsthetic in the painful extremities. No tendinous swellings about the wrists, or elsewhere, were noticed in any.

It is difficult to decide as to the exact influence of lead in the production of the arthralgic pains in these cases. Their character and seat, and their continuance in those that received no eliminative treatment, and that yet show evidence of plumbism, suggest they are in most of the 15 a mild form of the articular and muscle pains which were present in 47 of the 64 when these cases were thoroughly investigated over a year ago. Our knowledge of the peculiar morbid state underlying so-called lead arthralgia is too slight to permit us to assert that the same pathological conditions always exist. In most of the 47 the symptoms were originally those of aggravated neuralgia of the joints, bones, and intramuscular nerves. In not a few who were under observation for a considerable period and received no regular treatment, while the arthralgic pains were prominent, there were present symptoms suggestive of neuritis, such as sharp pains in the muscles and in the limbs in the course of the nerve trunks, often with decided tenderness on deep pressure; alterations in sensibility such as paræsthesia, hyperæsthesia, and anæsthesia; weakness in the limbs; rigidity, and frequent cramps in the muscles.

The electrical reactions were taken in several of these cases, but no quantitative or qualitative changes were found. The examinations, however, were made at too early a period for the negative result to be of much value in the diagnosis of the condition.

In none did the character of the symptoms suggest that the pains were of a gouty nature, nor do they now in the 15 under consideration. The smaller joints were unaffected, and no inflammatory appearances accompany the pain in the large joints. It is not unlikely that slight deposits of urates may occur in a joint, and no appreciable objective phenomena at once arise. Yet this condition could scarcely continue long without an inflammatory outbreak. There is no doubt that a special predisposition to gout exists in subjects of chronic plumbism, and it is not improbable that slight joint pains, with aching in the limbs, and muscular cramps, ephemeral neuralgias, headache, vertigo, and mental depression, occurring in such subjects, are sometimes symptoms rather of the gouty or lithæmic state induced by lead than of the direct action of that metal. Where doubt is felt, it is of diagnostic importance to examine the urine and blood-serum, quantitatively, for uric acid. I have, as yet, been unable to do this in any of the 15 arthralgic cases. It was probably excreted in deficient amount in at least 2. The urine of these has been more or less scanty, since pronounced symptoms of plumbism were present; it often deposits urates, and fits of the gravel occur. An unsuccessful effort was made to get specimens.

At the date of the preparation of the clinical analysis of the 64 cases, complete paralysis of the extensor muscles of the forearms (typical wrist-drop) had occurred in but 2; bilateral weakness of the extensors of the fingers existed in 1 other, and in 2 others there was slight loss of power in all of the extensors of the fingers and of the wrists, without actual paralysis. In the third-mentioned of these cases (1 of the 44) complete forearm extensor paralysis afterward occurred. In the 2 last mentioned the ataxia disappeared without paralysis ensuing. So that complete wrist-drop was met with in but 3 of the 64 cases, and it was not encountered in any of the other (15) cases of the chrome yellow poisoning traced to the same source, of which I have notes. This exemption among so many cases of pronounced plumbism in which the rarer condition—encephalopathy—occurred so frequently, is quite remarkable.

In none of the 3 cases did the paralysis extend to the upper arm or involve the supinator longus. Complete recovery has taken place in 1. In 2 of the cases power has been partially regained in the extensors of the wrist, so that the hand can be incompletely extended if the fingers are flexed into the palm, but the extensors of the fingers and thumb in both cases are yet too ataxic more than very slightly to extend these members or the hand itself

[1] The plantar surfaces in these cases were somewhat anæsthetic.

if the fingers are first passively straightened at the metacarpo-phalangeal joint. The paresis is greater on the left in 1; in the other, it is equally marked on both sides. Sensation is unaffected. Considerable atrophy exists in the situation of the paretic muscles in each case. Neither would come for electrical examination. It is presumed reactions of degeneration are present. 1 case is known to have taken for some weeks potassium iodide; the other received no treatment.

In 1 of the 44 in which typical paralysis agitans has developed, presumably as a result of lead poisoning, there exists, in consequence of weakness and stiffness of the forearm muscles, lack of complete extension of the hands and fingers on the wrist, more marked on the right. This case is of especial interest and worthy of detailed report, because it is generally supposed that although lead may occasionally originate tremor resembling somewhat that of paralysis agitans, the typical "shaking palsy," of Parkinson does not arise in consequence of poisoning by that or other metals.

Mrs. Mary McF.,[1] aged sixty-one years, occupation general housework. One of a family[2] of seven all of whom were severely poisoned from the same source. She had eaten the chrome yellow buns for nearly a year before symptoms other than cachexia, constipation, arthralgia, and slight colic, appeared. In June, 1886, she was seized with recurrent attacks of lead colic, lasting four to ten days, with intervals of about one week, during which slighter abdominal cramps, with nausea, vomiting, and constipation persisted. I visited her frequently in June and July, while investigating other cases of poisoning. All were studied with great care and it is absolutely certain that she was free from tremor then and before. In addition to colic, which persisted through the summer and autumn, attacks of generalized headache were now present with neuralgic pains in the joints and limbs. She lost flesh and strength, was depressed mentally, and sleepless. Tremor of the right hand and fingers was first noticed early in October, while plumbic symptoms were yet prominent. It was then slight and inconstant and appeared usually after mental or physical fatigue, but ceased on voluntary effort, by exercise of the will and during sleep.

I now lost sight of her until September, 1888. Since then she has been under constant observation. The following are the additional facts in her case from October, 1887, to the present.[3] She at no time received continuous treatment directed toward eliminating the lead. I had endeavored to persuade her to take potassium iodide. After a five days' trial she desisted, believing it aggravated colic and headache. Her health had always been robust until she suffered from plumbism. She had never had tremor before, nor had she ever received a physical injury or mental shock. No hereditary history of any neurosis is obtainable. Her people were sturdy Irish, who died rather of old age than of any disease. Umbilical colic and severe loin pain yet occur intermittently. She is dyspeptic and constipated, and has a marked blue line, with retracted gums and discolored teeth. Her skin is earthy-yellow and conjunctivæ are icteroid. There has been quite constant headache since the autumn of 1887, but it is less pronounced now than during the preceding winter and spring. Its situation is at times frontal and occipital but it is usually severest about the vertex. It is sometimes a deep-seated heavy ache, at others it is sharp and shooting. Recumbency and the approach of night greatly aggravate it. Sleeplessness and restlessness continue and she is disturbed at night by dreams of so frightful a character that she rouses the neighbors by her shrieks.

Tremor of the right hand and fingers increased rapidly in degree, and extended to the forearm and arm soon after its appearance. By the third month the right foot and leg were noticed to shake while she was seated. Seven months later (August, 1888), fine tremor appeared in the left lower limb. The facial muscles, and those of the tongue, eyeballs, neck, and left upper extremity, are entirely free from even slight tremor. The right upper extremity, especially the fingers and hand, is in a continuous state of almost uniform, coarse movement, which ceases instantly and absolutely—though momentarily—when voluntary effort is made with it, such as buttoning or unbuttoning the dress. If the effort is continued, after a few moments the tremor returns slightly, and it starts into redoubled violence on cessation of the effort, unless it be carried to complete and lengthy exhaustion of the arm muscles. Thus, having found that the constant jerking prevents sleep, she has for several months been in the habit on retiring of tossing the right arm about sometimes for hours, until, from sheer muscular weariness, tremor is no longer perceptible and sleep comes. It ceases absolutely during sleep. Mental excitement greatly augments it. All efforts of the will directed to control it are now ineffectual, and, indeed, rather increase it. If the tremulous hand is forcibly held, the movement becomes more violent after a moment, and tremor then appears in the opposite arm, and if she is sitting, that present in both legs grows coarser.

Her handwriting is suggestive. Always disliking writing, she had not before held a pen for years. This renders the zigzag character of the strokes in the specimen more interesting. For, were she used to the pen, the tremor, which ceases momentarily on voluntary motion, would perhaps have permitted her to complete the few words before it reappeared. As she is unaccustomed to writing, the will does not readily direct the hand. The movements are deliberate and the up and down strokes slowly and somewhat hesitatingly made. Time is therefore afforded the tremor to recommence.

[1] This case recently visited me several times in the medical clinic of the Jefferson College, and was shown by Prof. Da Costa to the class. I may state he is fully in accord with me both as to the diagnosis and as to the probable origin of the disease from lead poisoning.

[2] 2 of the 3 cases of wrist-drop occurred in this family.

[3] November 15, 1888.

Muscular weakness, stiffness, and some fixation of the limbs are present, but are not yet nearly so characteristic as the tremor. The grasp as measured by the dynamometer at different times recently, varied between 15 and 33 with the right hand, and between 35 and 40 with the left. Incomplete extension of the hands and fingers seems to be due largely to rigidity of the flexors, as force is required to extend passively the fingers at the metacarpo-phalangeal joints. The forearms are slightly flexed and stiffened at the elbow. There is some rigidity of the anterior cervical muscles, and muscles of the shoulders, which slightly inclines the head forward and causes stooping. In the inferior extremities the rigidity is greatest at the knee-joints and in the adductors of the thigh; more marked on the right.

Voluntary movement is slow, but the gait is as yet not festinating, nor is there propulsion. The facial muscles are unaffected. There is no festination of speech; articulation is slow rather than rapid, but it is monotonous and not syllabic. She is said often to "mix" her words. This I have not noticed. The knee-jerk is exaggerated on both sides. There is no ankle-clonus. Muscular nutrition is poor. The mechanical irritability of the muscles is increased, and there is quantitative diminution to both galvanism and faradism, especially the latter. This is most pronounced in the extensors of the forearms and in the right deltoid, but it is throughout more marked on the right side. Sensations of heat are absent. A feeling of constant chilliness has been present for nearly a year. It was as great during the summer as in cold weather.

Tactile sensation was carefully taken on three separate occasions, and, contrary to what is the rule in this disease, it was twice found very decidedly impaired. This was manifest on all surfaces of the arms, shoulders, and legs. It was not taken on the trunk or thighs. The whole surface of the right upper extremity was especially anæsthetic. This condition was noted in September, and again in the early part of October, 1888. Six weeks later, on casually retaking sensation in the finger-tips and hands, I was surprised to find the anæsthesia had disappeared. The cause for this is not clear. It is, however, unlikely that the loss of sensation had any direct dependence upon the paralysis agitans. Most probably it was of plumbic origin, had existed for some time, and was in process of disappearing when she came under observation this autumn. Lead was found in her urine in August, 1887. Albumin and sugar are absent.

The eye-ground was recently examined by Dr. Hansell, who reported: "R. $\frac{20}{XL}$; L. $\frac{2}{CC}$; opacities in cornea; double optic atrophy with choroidal ring and slight cup. The arteries and veins are small. Pupils normal."

Mental and physical depression is still a constant symptom in 10 cases. Headache is present in 8 of these, which before plumbic symptoms appeared were free from it. In several it is described as a diffused, deep-seated ache. In 3 it is severest in the frontal and occipital regions. In all of the 8, until quite recently, it was constant, with exacerbations and remissions. It is now of far less severity than formerly.

In 5 of the 8 the urine was examined for albumin, but with negative results. In one of these cases (Mrs. S.) in whose urine considerable lead but no albumin was found a year ago, and who had for months epileptiform convulsions of undoubted lead origin, subacute mania developed with hallucinations of sight and hearing and delusions of persecution. This condition still exists. In another (Mrs. G. W. L.), last seen in September, 1888, an eye-ground examination disclosed œdema of the temporal side of each nerve and tortuosity of the veins. Headache, worse at night, has been constant with her for more than a year. She now is melancholic, and has delusions of conspiracy. There are restlessness and sleeplessness at night and bad dreams. Her skin is sallow. The gums and teeth are still discolored by lead. There are arthralgic pains; dyspeptic symptoms; complete anorexia; a tense, full pulse; overacting heart, with a markedly accentuated aortic second sound. Her urine, recently examined, was of low gravity, but contained no albumin. Lead was not sought for, as the quantity furnished was small, and she would not take potassium iodide.

One other of the 5, a girl, aged seventeen years, had an attack of chorea, during January, February, and March, 1888, while decided cachexia, colic, and the blue line were yet present. She had never had rheumatism, and no family history of it or of chorea can be elicited. Her heart was functionally disturbed, but there was no murmur. None of these 3 cases received any regular treatment.

Curious spells of generalized tremor, of brief duration, have occurred in 1 of the 44 (Mrs. D., aged thirty-eight years), for the past sixteen months. An attack consists of a sensation of numbness starting in the wrists, and rapidly spreading over the body. There is then a feeling of impending danger, and immediately coarse, uncontrollable tremor seizes the head and limbs and continues for a half-hour or longer. Profuse diuresis generally takes place on its cessation. There is no loss of consciousness or tendency to spasm. The fit is not hysterical, nor are there at any time indications of the hysterical state. Motility and sensation are unaffected in the intervals. They were not tested during or immediately subsequent to one of the seizures. These spells occur about every three to five weeks irregularly; not at the menstrual period. Appropriate remedial measures directed to prevent their recurrence have the desired effect when pursued with regularity. She will not continue treatment sufficiently long to be entirely rid of them. This woman had con-

vulsions in April, 1887.[1] Five of her children were similarly affected about the same time, and four died.[2] Another was born in May, 1887, while symptoms of lead poisoning were yet present. This infant was undersized and cachectic at birth, and, though not suckled by the mother and every effort was made to raise it, it did not thrive. When aged four months, rhachitis developed; paroxysms of laryngismus stridulus were frequent, and death took place in convulsions in the tenth month.[3]

The appearance of the gums and teeth in 24 of the 44 cases is yet indicative of plumbism. But 3 of the 24 received eliminative treatment. A decided though fading blue line is present in 10, a distinctly bluish-purple line in 5, and a purple in 9. In 12 of the 24 there is much retraction and atrophy of the free margin of the gum, permitting considerable exposure of the neck and fang surfaces of the teeth, which, together with the crown surfaces, in the greater number of the 24, are yet discolored by lead sulphide. The free margins of the gum in many of the 24 are hemorrhagic. In these, slight friction causes venous oozing. The purple line is present in the situation previously occupied by the blue. In many of the cases I have watched this discoloration of the free gingival margin through its varied phases. It is of diagnostic interest to note that at first the so-called "line" consists of a number of fine black dots irregularly distributed, or an aggregation of them, forming a narrow bluish-black streak in the interdental portion of the gum, or in the extreme edge of the free margin, grasping one or more teeth, usually the lower bicuspids and molars, the teeth which are apt to be longest in contact with particles of food and about which decomposition of food elements is likely to be greatest.

Friction renders the pigmentation more distinct and perhaps causes slight hemorrhage. If the poisoning is slight and the absorption of lead ceases, the pigmentation slowly fades without destruction of the affected edge of the gum and no retraction of the gingival margin occurs. In several cases, three months after the lead ceased to be ingested, the narrow black streak or the fine dotting in the thin edge of the gum was distinctly visible, and at the end of a year the same thin edge was of a purple color.

Continued absorption of lead in considerable quantities produces an intense bluish discoloration of the buccal gingival margin several lines in breadth in the gums about the teeth in the upper and lower jaw. The lead sulphide, deposited in the lumen of the vessels, in their walls, and in the perivascular tissue, interferes with the nutrition of the affected portion of the gum and leads to its partial atrophy. The gums become exceedingly hemorrhagic so that the slightest friction causes venous oozing. Their dental margins in some situations become, after a time, fringed, and retracted from the neck of the teeth, exposing a part of the fang. When the blue line is decided, the crown, neck, and the denuded fang surface of the teeth are apt to contain a black deposit of lead sulphide, which persists for months after exposure to the poisoning has ceased, and then gradually fades, giving place to a yellowish-brown stain.

At a variable period following the cessation of the systemic absorption of lead, the extent depending largely upon the severity of the poisoning and whether efforts have been made to eliminate the metal, a bluish-purple discoloration succeeds the bluish in the affected portion of the gum, and it, in its turn, is succeeded by a purplish, and this by a red line entirely without any element of blueness.

In conclusion, I desire to express my indebtedness to Dr. Leffmann for examining the urine of a number of the cases for lead, and to Dr. Hansell for eye examinations.

2620 NORTH FIFTH STREET, PHILADELPHIA

[1] Her urine was slightly albuminous at that time. The albumin disappeared very soon after treatment was began to eliminate the lead, and has at no time been present since.

[2] *Vide* "Notes on Some Obscure Cases of Poisoning by Lead Chromate," THE MEDICAL NEWS, June 18, 1887.

[3] All of the five infants born of mothers exhibiting symptoms of lead poisoning during gestation had convulsions; four within two months after birth. Three of the five died in them. Another infant, born in July, 1888, of a mother who had pronounced lead poisoning during the early months of pregnancy, died in the fourth month in convulsions.

YELLOW FEVER.
AN EXPERIMENTAL RESEARCH ON ITS ETIOLOGY.[1]

BY PAUL GIBIER, M.D.,

ASSISTANT TO THE CHAIR OF PATHOLOGY OF THE MUSEUM OF PARIS, EX-HOUSE PHYSICIAN OF THE HOSPITALS OF PARIS, ETC., ETC., ENTRUSTED WITH THE MISSION OF STUDYING YELLOW FEVER BY THE GOVERNMENT OF THE FRENCH REPUBLIC.

IN the beginning of 1888, I presented simultaneously to the Academy of Sciences of Paris and to the Academy of Havana, the result of the researches that I had undertaken on yellow fever, begun in the month of November, 1887. Since that time I have given a lecture on the whole of my work on the subject to the Academy of Medicine of Paris.[2] In September, 1888, in consequence of these studies, the French Government, which four times before had honored me with its confidence for different medical investigations, commissioned me to go to Florida and study yellow fever which was prevailing there at that time.

[1] A paper read before the New York Academy of Medicine, January 17, 1889.

[2] *Vide* Bulletin Médical, of Paris; THE MEDICAL NEWS, The Lancet; Cronica Medico-Quirurgica, and Revista Clinica of Havana, etc., 1888.

When I arrived at Jacksonville, Fla., the epidemic had begun to diminish, but nevertheless, thanks to the courtesy of Surgeon-General Hamilton and of Dr. Porter, chief of medical relief at Jacksonville, I was able to examine as thoroughly as possible several subjects who died in the town, or in St. Luke's Hospital, where I had located my laboratory.

Before presenting the details of the cases I have observed, it will perhaps not be useless to examine a question which many physicians have asked themselves, and which they do not consider as being settled, viz.: *Was it veritable yellow fever which was observed last year in Florida, and in a few localities in the surrounding States?*

The relatively small mortality, and also the fact that the blacks were attacked in larger proportion as compared with the whites, have been the cause of these doubts. However, it is proper to remark that if in the West Indies they consider the black and even the mulattoes as having immunity from yellow fever, in the epidemics which have prevailed in the United States, on the contrary, the disease has been observed as well among the blacks as among the whites. (New Orleans, Memphis, Savannah, etc.) Moreover, in Jacksonville, a few days after the outburst of the epidemic, most of the white families left the town, comparatively few but negroes remaining. I shall add that it was remarked that, generally, the symptoms were less grave in the latter, and the fatality less considerable than amongst the white people.

Whatever it may be, I do not think that the question ought to be so simply stated; and according to my opinion, it is more complicated; and I think it is necessary to examine:

1st. If it was really yellow fever which was observed in the last epidemic at Jacksonville?

2d. In case of a negative reply, if it was a new disease?

3d. If all the cases registered were genuine? In other words, if there were not at the same time several kinds of fevers, as bilious, dengue, or malarial fevers more or less grave; and

4th. If yellow fever might not have assumed (at least in a certain proportion of the cases) a kind of hybridity, owing to the malarious character of the country?

Relying upon my observations, I will endeavor to answer briefly and in a general manner—not in detail—these several questions.

In limine I present it as a fact that many cases of yellow fever were observed in Jacksonville. For my own part, I have seen some cases absolutely characteristic, judged as well by the symptoms as by the anatomico-pathological lesions.

But it is not irrational to admit that a concomitant epidemic of bilious fever and many cases of malarial intoxication have existed simultaneously with yellow fever. On the sixteenth of November I made, at St. Luke's Hospital, the examination of a black subject who died on about the ninth day of his disease. I found the bowels normal; the liver was black instead of presenting the special color; the spleen was hypertrophied. I have no doubt that the patient succumbed to bilious fever; but, however that may be, it is certain he had not yellow fever.

At the temporary hospital (Sand Hills Hospital) Dr. Solace Mitchell showed me the thermometric charts of the patients, and in the greater number of them we noticed, by the intermittent form assumed by the fever (however the case terminated), that the paludal element awakened by the recent disease had stamped, as it were, its mark upon it, and made it assume one of those *hybrid* forms to which Prof. Verneuil, of Paris, has called attention.

It is likely that the cases, in diagnosticating which the observer hesitated, have been found, not in the centre of the town, but in the suburbs, and on the opposite side of St. John's River (South Jacksonville), where the sanitary condition is not calculated to preserve the inhabitant from malarial fermentations. It is easy to come to such a conclusion in view of the great number of shallow pools into which, as on the Ganges' shore, the neighbors throw their dejections. Observation VII., which I report hereafter, concerns a case which took place, precisely, in one of these localities; it seems, in my opinion, to belong to the category of pernicious fevers.

Before continuing this exposition I think it is necessary for me to quote the bacteriological observations that I have made. I regret having but a few cases to present; nevertheless these are interesting facts, and I may already say that they confirm entirely the more numerous observations that I recorded in Havana, at the end of 1887 and in the middle of 1888.

The *modus operandi* has been as follows: The substances which have been planted in cultures have been handled with all the precautions that are required; the liquids with sterilized Pasteur's pipettes and the solids (visceral matters) by means of a process that I have invented and which I will describe briefly. I obtain matter from the interior of a viscera by the use of a curette analogous to those which are employed for scraping the cervical cavity of the womb, with the difference that my instrument is curved instead of being straight. I cauterize, with a heated wooden-handled spatula, the viscera recently removed from its natural cavity, at the point into which I shall introduce the instrument, after having passed the latter through the flame. I plunge it into the parenchyma, revolve it several times, and withdraw it filled with pulp, which is then mixed with

dissolved agar-agar or gelatine. The rest of the operation is executed as usual. If the post-mortem is performed far from the laboratory, I dilute the pulp obtained by the scraping with sterilized water, which is used afterward for the cultures on plates, the Esmarch's tubes, or in the Gibier's matrasses.[1]

A large quantity of tissue may be planted in that way, and if the organs contain cultivatable microbes[2] it is almost impossible not to obtain a great number of colonies.

Obs. I. and II.—The pieces taken in the first two post-mortems have been altered because of the delay, caused by the quarantine, in receiving my instruments, which got to Jacksonville eight days after my arrival. I notice these two cases, observed at the Sand Hills Hospital, only in order to relate that they presented the characteristic lesions of yellow fever.

Obs. III.—St. Luke's Hospital, Nov. 2, 1888. Man, forty-two years old (white). Autopsy immediately after death. Taking urine from the bladder, blood from the heart (right and left ventricles), bile, and hepatic, splenic and renal substances, and black intestinal matter, I made cultivations of them. This is the summary of the results given by the cultures: Blood, sterile; bile, sterile; urine, sterile; kidneys (two Esmarch's tubes), first tube, sterile; second tube, one colony of a small micrococcus. The liquid at the bottom of the tube, although clear, contained some large and long bacilli. Spleen, three colonies of a large micrococcus. Liver (two Esmarch's tubes), one tube sterile, the other contains four colonies of large and long bacilli. *Intestinal contents:*, black, neutral, different microbes in the cultures, but none dissolving the gelatine.

Remarks.—In this observation, the intestine did not contain the bacillus I found in such large quantity formerly in Havana. If this bacillus is really the cause of yellow fever, we must admit that, under still unknown influences, it may disappear after having produced the special intoxication. The same phenomenon is observed in a large proportion of cases of Asiatic cholera in regard to the comma bacillus of Koch. It may be thus satisfactorily explained in an affection which has lasted eight days.

As in my former observations, the blood did not contain any microbe. I shall add that the microscopical examination of it showed nothing abnormal either in the fresh state, or in desiccated or fresh, variously colored preparations. *It has been the same in all my observations without any exception.*

As for the different microörganisms which developed in the cultures in the viscera, the number of the colonies was so small, and so various their composition, that we may admit that an accidental infection took place during the manipulations. But with the cultures in solid *media* there is no reason to fear the same errors as with the liquids. In the same conditions a liquid *medium* would have been full of organisms which would have developed freely. In the solid *media*, on the contrary, a germ fortuitously introduced (during the various manipulations undergone by the preparations) remains where it is caught, but cannot invade the whole of the culture. If a microbe does exist, which might proliferate primarily in liquid and not in solid *media* (which as yet has not been seen), this microbe could multiply easily in the bottom of the Esmarch's tubes, where, after coagulation of the agar-agar, a certain quantity of bouillon accumulates always.

Although I admit (as I have in my preceding publications) the introduction of the microörganisms into the viscera, as a possibility, owing to the alterations of the mucous membrane, I consider the cultures of the liver, of the spleen, and of the kidneys of the preceding observation as having remained sterile.

Obs. IV.—Duval Co. Hospital, November 3. Man, forty-five years old (white). Carried to the hospital in a semi-delirious state, increasing till death. Antecedent history obscure.

This case, for which I am indebted to the kindness of Dr. Drew, attending physician, did not present any characteristic anatomico-pathological sign. Post-mortem one hour after death. The skin and the subcutaneous cellular tissue presented a yellowish coloration. The urine, which could not be examined during the short sojourn of the patient in the hospital, taken and analyzed after death, contained a large amount of albumin. No possibility of knowing if the patient was catheterized before his admission into the wards. A muco-purulent discharge from the urethra. The bowels were almost empty, no congestion; the colorless matter which clung to its walls was neutral. The stomach, the walls of which were injected, contained a small quantity of a brownish liquid with some dark particles. Kidneys congested. Liver brown.

Some cultures were made with blood, bile, urine, kidneys, spleen, liver, and gastric and intestinal contents. Results of the cultures: *Blood:* sterile. *Urine*: a few colonies, a *micrococcus* of a medium size, growing on the surface of the agar, small colonies, poor, irregular, not liquefying the gelatine. *Bile:* rare colonies of a *torula* growing slowly. *Spleen:* four colonies of a large *micrococcus* and a colony of a mycelium (accidental infection). *Kidneys:* sterile. *Liver:* sterile. *Stomach* and *bowels:* common microörganisms. Do not liquefy the gelatine.

Remarks.—It is very doubtful if this patient succumbed to yellow fever.

Obs. V.—Case kindly furnished by Dr. Webster. Woman, thirty-five years of age (slightly colored,

[1] *Vide* on these matrasses: Bulletin Academy of Medicine of Paris, September, 1888, and Journal de l'Antisepsie, Masson, Publisher, Paris.

[2] With a smaller curette the same process may be used for experimental work generally, and especially in tuberculosis, with the viscera of small animals, as the guinea-pigs.

"octoroon"), died at the jail, after four days' illness. She had presented the characteristic symptoms of yellow fever (black vomit, large amount of albumin, etc.).

Nov. 7. Autopsy, eight hours after death. Icterus very intense; yellow coloration of the adipose tissue. Liver: "nutmeg" or "café au lait." Spleen small. Kidneys congested. Bladder empty.

The stomach and bowels contain a large amount of black liquid, *acid* in the stomach but decidedly *alkaline* in the small intestine and neutral in the large. Cultures of blood, kidneys, liver, spleen, and intestinal contents. The cultures of the blood remained sterile. The kidneys, the spleen, and the liver contained a certain number of *diplococci*, the colonies of which spread quickly over the surface of the agar-agar, under the semblance of a semi-transparent cloud; they dissolve the gelatine very rapidly. It is the first time I saw this microörganism. I did not find it in the bowels. It is also the first time that I found a microbe in the parenchyma of the viscera of a subject dead with yellow fever; but I must call attention to the fact that the autopsy was performed eight hours after death, in a surrounding temperature relatively high (the interior of the subject was still warm); all conditions very propitious for the growth of the bacteria of decomposition.

Some particles of the contents of the bowels, taken from different parts of the digestive canal, were diluted with sterilized water, and with them I made cultures on gelatine in my matrasses. Notwithstanding the large dilution, the colonies were so numerous that after twenty hours the gelatine was entirely dissolved in the first two matrasses. In the third (fourth dilution) on 106 colonies I counted 98 which liquefied the gelatine.

I call attention to the importance of this fact: *all those liquefying colonies were formed by the microbe that I had isolated in Havana.*

Obs. VI.—St. Luke's Hospital, November 13th. White man, forty years of age. Died the eighth day of his illness, after having presented the classic symptoms of yellow fever. Autopsy one hour after death. Cultures with blood, urine, kidneys, spleen, liver, intestinal contents, which were black and slightly *alkaline.*

Results.—The cultures of the blood, of the renal, splenic, and hepatic pulps, remained absolutely sterile. Cultures of the urine contained some colonies of micrococci, but I must add that the patient was catheterized several times at the hospital.

The cultures of the contents of the bowels taken, as usual, from differents points, presented only common microbes.

Remarks.—This seems to have been a genuine case of yellow fever, but the pathogenic *bacilli* had disappeared from the intestine when death supervened.

Obs. VII—Nov. 14. Case due to the courtesy of Dr. Kenworthy. Man, thirty years of age (black), living in the swampy locality of South Jacksonville. The day before, twenty-two hours before succumbing, he had a violent chill, followed by a very high fever (109° F., axillary). A few days before, he had a slight indisposition but recovered.

Autopsy at 4 o'clock in the evening, one hour and a half after death. The liver seems normal, the heart also; kidneys very congested, spleen moderately hypertrophied; urine very albuminous. The intestine contained a whitish matter moderately abundant, alkaline, and the stomach a small quantity of slightly colored liquid. No congestion.

Cultures made with blood, spleen, liver, and intestinal matter. It was not possible to obtain urine.

Results.—The cultures of the blood, of the kidneys, of the spleen, and of the liver, remained sterile. The cultures of the intestinal contents were strewn with colonies almost exclusively composed of large and long bacilli, which did not dissolve the gelatine. Their colonies grew at the surface of the plates, with the aspect of a light pellicle, more or less irregular, and in the interior of the medium of the culture they were regularly spherical.

Remarks.—This seemed to have been a case of pernicious fever; albuminuria is observed in those fevers, as well as in the grave form of bilious fever, and in yellow fever; this symptom cannot, consequently, be used as an absolute criterion for the diagnosis. The indisposition which preceded a few days before, was likely a slight form which appeared before the fulminant access. It is not usual to see yellow fever striking down so suddenly its victims.

Now what is the value of the long bacillus found in the intestine? I cannot tell at present. I report the fact, only, with the hope it may guide some other researches.

After having related the preceding observations, it remains to draw some deductions from them. At first, I recognize that the number of my bacteriological analyses, in this second series, is very limited, especially if we consider that, of the five, I have hardly three undoubted cases. However, is it not remarkable to see that of these three cases (Obs. III., V., VI.) that in which death was more rapid (four days, in Obs. V.) was the one in which the intestine contained the black and characteristic matter, and presented, in such an extraordinary abundance and almost exclusively, the same bacillus which I have seen in several yellow fever subjects in Havana?[1]

I recall the fact that I discovered this microbe first in some Spanish soldiers who died with yellow fever in the military hospital of Havana, and, several months after, in some foreign sailors who succumbed to the same disease in the civil hospital of the same city. I did not find it in subjects dead with other diseases in the latter hospital. Now, after a year, I find it again, as it were, in the state of a pure culture, and in great abundance in the intestine of a subject who presented the symptoms and lesions of genuine

[1] After my first investigations had been published, Dr. G. M. Sternberg also found the same bacillus in three cases of yellow fever in which he looked for it. (*Vide* Cronica Med. Quirurg. de la Havana, June, 1888.)

yellow fever, and this in Florida, at Jacksonville, several days' journey from Havana.

I recall, also, that the cultures of this bacillus exhale an odor quite similar to that which I have remarked several times in black vomit; also, that its biological qualities are entirely in accord with the physiology of yellow fever itself, and in certain conditions I exposed formerly, it blackens the bodies it comes in contact with, so much so that some liquid cultures have the appearance of the matter of black vomit. But I am far from pretending, although it has been claimed, that the last character, no matter how suggestive it may be, is pathognomonic. Of course, my attention was attracted by this melanogenous property—which, however, does not always appear—but I was, above all, struck by the very considerable quantity of the bacillus in one of the first cases I analyzed.

Thus, I think I am right in saying that the presumption that this bacillus is the cause of yellow fever tends to become a certainty.

Besides, I must notice that in the cases in which autopsy took place early after death—as well in Havana as in Jacksonville—the blood, the liver, the spleen, and the kidneys have been constantly found free from microbes. This fact strengthens the theory that I have supported, viz., that yellow fever is an intestinal infection which must be treated *from the very beginning* with the evacuants and disinfectants of the intestines, as bichloride of mercury, naphthalin, and tannic acid.

However, two objections may be presented, which I must answer: How is it that the microbe, supposed to be pathogenic, is not found in every case after death, and, if it has disappeared, how shall we explain the persistence and the aggravation of the accidents? Secondly, if yellow fever is a disease, the germ of which grows exclusively in the intestine, how shall we explain albuminuria? Let us examine the facts.

We do know that when a microôrganism has saturated any medium of culture, its growth stops. If another microbe is introduced, and grows in the medium transformed in that way, the first often disappears. This could explain the possibility of the disappearance (at any variable moment) of the microbe of yellow fever. I propose, at the very first opportunity, to analyze the dejections of several patients from the first day to the last. I should not be surprised to find my microbe only in the first period of the disease, at least in a certain number of cases.

As to the persistence, and eventually the aggravation of the accidents, they, in all probability, depend upon the more or less grave import of the lesions. The latter are due to the poisonous products, to the ptomaines secreted by microbes and absorbed by the bloodvessels of the intestine, and more especially by the radicles of the vena porta.[1] We know that though the microscope and the cultures show the absence of bacteria in the liver, this gland, into which the blood of the vena porta first flows, undergoes, nevertheless, a fatty degeneration analogous to the one observed in certain cases of poisoning *per ingesta*. The spleen, on the contrary, is of normal appearance, unless there is malarial complication or secondary infection. And, if the kidneys are congested and give passage to albumin, it does not mean that they are directly attacked by the bacteria; in typhoid fever, for instance, which may be considered as an infection primarily intestinal, albuminuria is observed without finding in the urine, at least in the beginning, the specific bacillus so easy to ascertain otherwise. Certain kinds of poisonings, also, produce albuminuria (lead, phosphorus, cantharides, etc.).

Before finishing, I desire to remark that in my examinations I have ascertained that the contents of the intestine were alkaline or neutral; they were more decidedly alkaline in Case V., in which my bacillus was so abundant. I believe that the coloring matters contained in the intestine must contribute to induce observers to commit many an error on this subject; these matters color the test-paper yellowish-red, but they do not always discolor the same chemically. I do not pretend, however, that the intestinal contents might not prove acid (but then my bacillus would have disappeared from the intestine).[2] I once observed, in the civil hospital of Havana, on a subject who died from a mitral affection, that the intestinal contents were clearly acid, whilst the liquid contained in the stomach was alkaline. The post-mortem was performed an hour, or two at the most, after death.

It would be of the greatest interest to continue these researches. The experiments I have made on my bacillus have already given the explanation of the fact that yellow fever remains endemic on the seashore of hot countries and not in the interior; and of this other fact also, that an infected vessel may hibernate in glacial regions without losing the property of communicating yellow fever when she returns to a hot zone.

Other experiments, which I intend to publish later, induce me to think that, if the bacillus in question is really the cause of yellow fever, it would not be impossible to protect against that terrible disease the populations of the countries exposed to the epidemics.

---

[1] As in poisoning by venomous mushrooms, notwithstanding the evacuation of the ingested substances, the visceral lesions are produced, and sometimes cause death.

[2] This bacillus does not live in an acid medium. This may be another cause of its disappearance from the intestine.

A CASE OF ADDISON'S DISEASE.

REPORTED BY R. W. GARRETT, M.D.,
PROFESSOR OF ANATOMY, ROYAL COLLEGE PHYSICIANS AND SURGEONS, KINGSTON, ONTARIO

OWING to the rarity of this disease it is very seldom an opportunity is afforded for observing the clinical history of a typical case; and it is still more rare to be able to follow up such a history with an autopsy. Under the circumstances I thought a publication of a synopsis of notes taken by his medical attendant and myself, together with the results of the post-mortem and microscopical appearances of the structures involved, would prove interesting as well as instructive.

M. D. S., aged thirty-four, five feet seven inches high, married, of a stout, strong, athletic build, muscles highly developed, chest broad and deep, and other appearances of an unusually well-proportioned young man. Family history excellent. As a child, he always had good health, having had no serious illness, except the usual diseases of childhood. During his early years he superintended his father's farm, but for the past six years he has been manager of a large sash and door factory. Up to the beginning of last July his health was excellent and with few exceptions was always able to attend to all the duties such a large concern would require of a manager. In addition he was a member of rowing, base-ball, and foot-ball clubs in each of which he took an active part, and for which his athletic build made him exceptionally fit.

Three or four times in the last few years he had an attack of diarrhœa with colicky pains lasting two or three days but in the intervals the bowels were quite regular. Nearly a year ago he had an attack of migraine for three days. Last June as an officer in the active militia he went to Gananoque, where in company with his battalion he camped for twelve days. During that time I had daily opportunities of seeing him, and I frequently heard him say that he felt remarkably well, that he had an enormous appetite, and his only trouble was constipation.

On July 2d, in the absence of his physician I was called to attend him for a mild attack of typhlitis lasting a few days and terminating in a copious diarrhœa. It was at this time I noticed a peculiar color in his face, a dull brownish look, but attributed it to the sunburn acquired at camp; I also noticed a weak pulse out of all proportion to the severity of his late illness.

Subsequently he picked up considerable under tonic treatment, but never regained his natural color. About the middle of August he was seen again, when he complained of weakness and disinclination for doing any kind of work; his face and hands were still discolored, eyes rather sunken, pulse small and weak, otherwise he seemed to be in good health.

These symptoms became intensified as time went on and, in addition there developed a restless, nervous condition.

On September 30th, in consultation, his case was carefully investigated and from notes taken I extract the following: body well-developed, muscles large but flabby, abdominal wall thickened; brownish discoloration of face and neck terminating abruptly above where the hat sheltered the forehead and below at the upper margin of the collar. Pigmentary deposits, irregular in outline, were also found in the right iliac region where sinapisms had been applied during the attack of typhlitis, also on the genitals, particularly the dorsum of the penis; the backs of the hands were also discolored while the palms were a light yellow tinge terminating abruptly where the coat-sleeve covered the wrist. With these exceptions the skin over the whole surface of the body was natural in color and feel.

The eyes were dull and lustreless, somewhat sunken, without pigmentary deposits, the sight normal. The tongue was clean; the mucous membrane of the mouth was of the ordinary color without any discoloration; the lungs perfect; the heart remarkably feeble in action, the systolic sound being almost wholly valvular. · Abdominal palpation and percussion gave negative results; pulse 100, weak, small and irregular; appetite poor, capricious, and there were frequent complaints of nausea but no vomiting. Absence of any appearance of œdema. Marked depression and enfeeblement of the nervous system with restlessness, the patient remaining quiet scarcely a moment; profound asthenia, out of all proportion to his general condition, with a tendency to faintness on sitting up. His favorite position was on the back, knees drawn up, the calf of one leg resting on the knee of the other, the position of the legs being reversed every five or ten seconds; great lack of energy both mental and bodily; feeling tired on the least exertion; loss of memory, particularly of recent events, for instance, he could not give an account of his symptoms—if asked if his bowels had moved that day would say "let me see," then would try to think, and in all probability would in a moment or two start to talk about something else, in fact, he could not recall any recent event without a distinct effort. Bowels regular and natural; urine normal.

During the remainder of his life (two weeks), the symptoms became intensified, except the bronzing which, in the opinion of all those who saw him, became lighter in shade. On the morning of the 13th of October, he had an attack of syncope which was overcome by hypodermatics of stimulants. The same evening, after a fairly good day, suddenly profound prostration set in, total inability to stir the body, or even move a finger; the extremities became cold, the wrist pulseless, and at 12.30, of the morning of the 14th, after swallowing a few drops of brandy and milk he expired from cardiac asthenia. His intelligence remained clear up to the moment of death. Duration of the disease three and a half months.

The treatment throughout was purely symptomatic, tonics at first, particularly quinine and nitro-hydrochloric acid. The nausea was always relieved by bismuth and cerium, and the attacks of hiccough he always checked by eating a few cold grapes. Stimulants did harm, increasing the restlessness and nausea. Any kind of a purgative caused profound depression. Twenty grains of potassium bromide with five grains of

Dover's powder always gave a quiet refreshing sleep, lasting throughout the whole night and well into the next forenoon; in fact, this combination acted like a heavy dose of a narcotic.

He became tired of every kind of food, except buttermilk which he drank in large quantities, always, he said, relieving the thirst and nausea.

In regard to the cause, there is none known, nor anything to which the disease might be attributed. It might be mentioned that six years ago he was thrown from a horse and fell on his back. Three years later an abscess formed in the region in which he sustained the injury. It was evacuated; healed up rapidly, leaving a depressed scar.

In company with Hon. Dr. Sullivan and Dr. Oliver, the attending physician, I conducted the post-mortem examination, and to Dr. Sullivan, who made copious notes, I am indebted for the following:

Autopsy, twelve hours after death, revealed marked rigor mortis. The body was muscular and well-formed, without the slightest evidence of emaciation. The only mark was a large circular, depressed scar over the right kidney, which marked the site of a former abscess. The bronzed color on the face, hands, genitals, and right iliac region had changed to a lighter shade.

The opening incision showed about one and a half inches of fat in the abdominal wall; the muscular tissue was healthy and well developed. The subperitoneal fat was abundant, and the omentum well covered with adipose tissue. The liver darker in color but normal in density and volume; the gall-bladder empty, contracted, and diminished in size. The spleen was somewhat enlarged, the pancreas and duodenum normal. The stomach was empty, shrunken, but healthy in structure. The small intestine was somewhat narrowed and slightly congested in parts; partially filled with liquid. It had a general bronzed appearance, very marked in some portions of the ileum, looking as if stained with bile, but contained much less flatus than usual.

The large intestine was healthy; there were some adhesions around the cæcum, indicating a former typhlitis, but the vermiform appendix was congested, firmly adherent to the caput coli, and diminished in size nearly one-half.

The suprarenal capsules were readily detected by their size and hardness, and were, along with the kidneys, carefully dissected out, together with a portion of the aorta. The kidneys were normal in size, the capsule peeling off readily, and on section were dark purple in color, but in no way affected in structure. The right suprarenal capsule was more than three times its normal size, irregularly nodular, and containing a substance arranged in compartments, having a uniform grayish-white, caseous appearance. The investing membrane was thick and dense. The left capsule had increased in size in a vertical direction, was harder, and had, in addition to the caseous masses, firm nodules, cutting with much resistance, and feeling almost like cartilage. There was much fibrous thickening in the neighborhood, extending to the solar plexus, semilunar ganglia, origin of superior mesenteric, and aorta. This fibrous new-formation surrounded the cœliac axis in a matted mass, narrowing the lumen of its branches, and when removing this mass with the aorta the nerves of the sympathetic could be seen like strings of catgut extending through it. Extending upward, the matting could be traced along the aorta toward the arch, but not downward.

Some few mesenteric glands in the neighborhood of the suprarenal capsules were enlarged, somewhat softer than natural, but macroscopically had no appearance of caseous degeneration. Except as stated, the peritoneum was healthy, not the slightest appearance of fibroid degeneration. Peyer's patches and solitary glands showed no changes.

A noticeable feature of the autopsy was the almost entire absence of blood; the vena cava, and other large bloodvessels were freely divided, but a small napkin was more than sufficient to keep the parts clean during the lengthened examination; the peritoneal cavity was more than naturally dry.

According to promise made to friends who granted the autopsy, the thorax and cranium were not opened, and for the same reason no extensive dissection was made of any of the abdominal organs.

Dr. Clark, superintendent of the Asylum for the Insane, kindly prepared and mounted several microscopical specimens taken from the right capsules, and from his notes I have extracted the following:

When the diseased organ was cut across, the grayish material formed the chief part of the mass, and there were scattered throughout this yellow masses larger than peas. Cretaceous particles were also apparent when the specimen was being prepared. Sections from the gray part showed it to be made up of irregular cells held together by a fibrillated structure. In the yellow bodies the fibrillæ were not apparent, the mass being made up of granular matter and degenerated cells.

RESUSCITATION AFTER APPARENT DEATH.

BY A. H. P. LEUF, M.D.,
OF PHILADELPHIA.

WHEN a cell or number of cells die, it is called a cellular death. When the body as a whole has ceased to act, it is somatic death. Somatic death is a fact when, what Watson has appropriately called the "tripod of life"—*i. e.*, the brain, heart, and lungs, no longer functionates. At this time, cellular death has only partly occurred. In warm weather, as on a hot midsummer's day, cellular life may continue for hours after somatic death. Especially is this the case in sudden death.

The distinction between somatic and cellular death is of the utmost importance, and should always be in the mind of the physician. It explains the resus-

citation of so-called dead persons. There is a case on record of a man lying in the sunshine at the bottom of a small, quiet, shallow stream for fully half an hour before he was taken out, and efforts made at resuscitation, which proved successful at the end of several hours' unremitting labor.

Dr. Jerome Walker, of Brooklyn, was once called to attend a child suffering with diphtheria. It died while he was present. Consciousness was gone, the heart and lungs had ceased to act, the pupils were dilated, and, in fact, the child was a corpse. He tarried for a moment, and then left for his office, whence he returned with a faradic battery. This he applied to the pneumogastric nerve and chest muscles. Fully twenty minutes had elapsed since the death of the child and the beginning of the electrical application. After a while his efforts were crowned with success, for there were a few gasps and a flicker of the heart, but the officious and ignorant relatives compelled him to desist, and the child passed away into complete cellular death.

Probably one of the most remarkable of this class of cases is one which occurred in the practice of the late erudite and philosophic Dean of the Long Island College Hospital, Professor Samuel G. Armor. I record it, as I had it more than once from his own lips.

The patient was a well-to-do man with wife and children. He had purchased a pain-relieving remedy of a travelling quack. Its basis was cannabis Indica or Indian hemp. He swallowed an overdose, taking it in drachms instead of drops. In time he developed all the symptoms of narcotic poisoning. In spite of all efforts on the part of the attending physician he died. The grief-stricken wife and children wept at the bedside of the dead man. Dr. Armor was present, and at that time was Professor of Physiology in one of the Western schools. At last all left the death-chamber, except Dr. Armor and a negro attendant.

Looking out of a window the doctor mused for some time over the sad ending of his friend and benefactor, for such he had been, and came to the philosophical and scientific conclusion that his friend was somatically dead, to be sure, but that cellular life must still be active, for the room was warm. He thought that if the respiratory and circulatory functions could be maintained by external influences till enough of the poison had been eliminated by the cellular activity, the patient might still survive.

Dr. Armor stated to me that, if required, he would solemnly swear that the shortest possible time that could have elapsed from the time that death was declared until he concluded to make efforts at resuscitation, "*was at least one hour.*" In this estimate he allowed for all the circumstances that might cause time to be overestimated, and felt certain, in his own mind, that he had fixed the time at less than it had actually been.

Bottles of hot water were applied to the limbs; hot water, red pepper, and whiskey were injected into the bowel, and the same poured into the stomach. Artificial respiration was begun. When the Doctor tired, the negro relieved him, and so they alternated. Occasionally a stethoscope was employed to detect a possible heart-flutter. All was of no avail. After two hours' effort, the body continued lifeless. Hope had fled. The negro, however, continued while the Doctor rested. The desire to save his friend, if possible, and the scientific aspect of the question that had been raised, caused a renewed attempt. More injections were given, and more hot bottles were applied.

More than three hours had elapsed, and again was the attempt abandoned, and once more vigorously made. After nearly four hours of hard work, and when about to desist for the third time, Dr. Amos thought he detected a slight movement of the lips. Soon, again, he was quite positive that he saw it. Again he noticed it after a long interval, and then was certain of returning life. The stethoscope discovered an occasional light, muffled sound over the heart. More injections were given, and efforts at artificial respiration were redoubled. At last the gasps became pronounced, the heart-beats more frequent, the respiration deeper and more regular, until, eventually, respiration and circulation were reëstablished, but at a slow rate. Consciousness was not regained for hours, but eventually it returned.

Dr. Armor's description of his own feelings, and those of the family, and negro at this time may be better imagined than they can be told. The patient was alive and well over a score of years afterward; in fact, he was alive and well but a few years ago, and prominently interested and well known in New England financial and banking circles.

These cases teach the difference between somatic and cellular death, and demonstrate that when "life" is extinguished by a sudden interruption of the functions of the brain, heart, and lungs, without any organic change, there is hope for recovery if proper efforts are made and persevered in, for hours, if necessary.

The intelligent practitioner will always bear in mind the distinction between these two kinds of death. Just as we have so-called functional diseases which are not accompanied by any known or detectable lesions of structure, so, also, do we have functional somatic death without structural lesion. In all such cases it should be our duty as physicians to attempt the return of "life" until there is undoubted evidence of cellular death; for instance, rigor mortis would seem to be a reliable sign, judging from the present state of our knowledge on the subject, though coming investigation may show that even this is not necessarily a positive death accompaniment.

There can be no doubt about there being a number of deaths annually that could be prevented by persistent efforts at resuscitation. It seems to me that there is no more imperative indication for the necessity of

persistent efforts at resuscitation than the knowledge or belief that "death" is due to the cessation of the gross bodily functions without structural lesions. In all such instances efforts to bring back life should continue till there is positive evidence of death in the full sense of the word, and this I should consider proven after the appearance of *post-mortem* lividities and *rigor mortis*.

Many cases of the kind that I have mentioned could be adduced, but a few should be sufficient.

A proper question is as to the different modes of exciting the heart's action; among the many methods being Corrigan's button, heat and cold to the epigastrium, cardi-puncture, intracardiac injections, hot and cold douche and immersion baths, and flagellations.

129 S. THIRTY-SIXTH STREET, PHILADELPHIA.

MEDICAL PROGRESS.

The Treatment of Acute and Chronic Tonsillitis.—On Dec. 4th SIR MORELL MACKENZIE visited the throat clinic at the Edinburgh Eye, Ear, and Throat Hospital. He examined a number of patients, and in the course of a short clinical lecture made the following remarks:

"There are two forms of acute tonsillitis, the superficial and the deep. All of you must be well acquainted with these familiar diseases, but perhaps you will like to hear my experiences of the treatment. The superficial is not very serious. It is, however, painful, and it is apt to recur. A person who has had it once is very likely to have it again. This is true of both forms of tonsillitis, but it is particularly so of the superficial. The interior of the follicles becomes inflamed and secretes an unhealthy mucus, and they never thoroughly recover. In all inflammations of mucous membranes the membrane does not really get well, though it may appear to do so. A celebrated French surgeon has said that he does not believe that a person ever really recovers after a gonorrhœa. This is true of the follicles of the throat. A person who has once had acute tonsillitis never really gets well, though he may appear to do so. The treatment, therefore, is important. One of the most popular remedies is aconite—originally, I believe, a homœopathic drug, but now used extensively by allopaths (though I object to the term)—and strongly recommended by Dr. Ringer. It has certainly never, in my hands, proved to be of the extraordinary value which he asserts. On the other hand, I have found guaiacum, which used to be given in the form of the ammoniated tincture, very efficient. I recollect a Manchester surgeon, Dr. Crompton, who used to come a good deal to the Throat Hospital about the time it was founded, telling me I should find much more benefit by giving it in the form of a powder; and I did so, letting the patient take a pinch of the resin. This was rather disagreeable, and after a time I had it made into lozenges containing about three grains in each. In this form it makes an excellent remedy. Nine cases out of ten will get rapidly well if one of these lozenges is given every two hours at the outset. I sometimes also apply locally a little bismuth and opium, or an eighth of a grain of morphia with a quarter of a grain of starch, because the problem is not only to cure the patient, but to keep him comfortable till he is cured. Sometimes the guaiac causes a little diarrhœa, which is not altogether disadvantageous, but the morphia is usually sufficient to check it. What I have said about guaiac applies to acute inflammations of any part of the back of the throat. Dr. Home has said of guaiacum, "Instar specifici in hoc morbo operatur." It is really specific. I have used it for fully twenty years, and I assure you it is one of the best remedies you could have. It causes a slight stinging sensation, and this is an additional reason for using the morphia.

"Occasionally this superficial or follicular tonsillitis if not checked passes into the deep or parenchymatous form, and the structure of the gland becomes very much affected. When the deep inflammation occurs you must bring it to an abscess as quickly as possible, and open it. Trousseau has pointed out that some inflammations *begin* in the deep part of the gland, and these you cannot check, as a rule, though you may sometimes succeed with guaiac. I have done so in two cases lately. We are usually, however, called in too late. When you find you cannot stop the disease, give inhalations of benzoin, hop, or conium, and apply poultices to the outside of the throat. Directly you can find fluctuation, make an opening. As the tonsillitis develops it prevents the patient opening his mouth, and there is sometimes difficulty in getting at the abscess. This is the reason why surgeons sometimes have to let the abscess burst, but this should be avoided, if possible, because it has been followed by dangerous and even fatal hemorrhages. I generally use a curved and guarded bistoury, of which only the last quarter of an inch has a cutting edge, but an ordinary bistoury, the greater portion of the edge of which is covered with diachylon, may also be used. The incision is made with the cutting edge directed inward to the centre of the mouth. You must never cut outward, for there is then the danger of wounding the carotid. I would recommend you to incise in cases in which you may not be quite certain of fluctuation. A slight puncture, even if pus is not evacuated, does no harm. The use of leeches was at one time common, but Louis the French physician proved that they did not cut short the disease by more than one day, and therefore their application was not desirable. Leeches have the effect of increasing the inflammation rather than otherwise if less than six are applied.

"Chronic tonsillitis, or hypertrophy of the tonsils, proceeds from two causes. A large number of the cases are the result of a low form of inflammation occurring in childhood. The structure in childhood is very prone to become inflamed. If the tonsils are considerably enlarged, it is important to remove a portion of each. You should never speak of "cutting out the tonsils," as this sounds very alarming to the patient and his friends. Say that you mean to remove only "the diseased and enlarged portion." It is a consideration when you should do this. How much enlargement should there be before the operation is performed? First of all, the question of size is entirely relative. In a large throat the tonsils may grow to a considerable size, and the patient still do quite well. In a smaller throat this would not likely be the case. If the tonsils touch each other, you can have no doubt as to the propriety of taking away a piece. If adult patients come to you with the tonsils slightly enlarged, it is an

important question whether you should cut off a portion or not. If the enlargement is associated with frequent attacks of acute inflammation, you ought then to cut away a piece. There is another condition which requires a similar proceeding. When the follicles of the tonsil are much enlarged, you cannot cure it except by taking off a section, which may be not more than one-eighth of an inch thick. You thus clear away the walls of the deep follicles and get a flat instead of a "worm-eaten" surface.

"As to the method of operating, many surgeons do it with a bistoury, and Sir William Ferguson, a great surgeon, for whom I had the greatest admiration, used to perform it in this way, but it was terrible to see the patient struggling with the mouth half-full of blood before the operation was completed. Great surgeons will do all they can with a knife instead of what they call a "machine." I always perform the operation, however, with "a machine," a tonsillotome. The particular form I use is a modification of Physick's. The great advantage of this is that its mechanism is quite simple, and my modification enables the handle to be fixed on either side of the blade, so that the operation may always be performed with the right hand if the operator desires. As a general rule, lightness of touch is the chief desideratum in operating, but in tonsillotomy it is the reverse. Heaviness of touch is the important thing. The tonsillotome must be pressed well over the tonsil, which is also to be projected into it by pressure with the left thumb placed under the angle of the jaw. I once had a colleague who could do very little else, but he took off tonsils marvellously, and as I watched him I observed that it was this heaviness of touch that made him so successful. If you do not attend to this, you will not take off nearly so much as you desire. Patients have come to me a week or a fortnight after the performance of the operation by another surgeon, saying that the tonsil has been removed but has grown again! This, of course, means that enough was not removed at the operation. It is most important to take off enough.

"Hemorrhage from this operation is rare, but it has occurred, and the carotid in some instances has had to be tied. I once had a serious hemorrhage to deal with some twenty-five years ago. The usual styptics, and even the cautery, failed to relieve it. At last I tried a remedy which I have used ever since with perfect success. A chemist had informed me a short time before that a small quantity of gallic acid would prevent tannic acid dissolving. I mixed two parts of the tannic and one of the gallic in a little water, and gave the patient two teaspoonfuls, telling him to sip them slowly. The bleeding stopped almost at once. We have since used the same preparation at the Throat Hospital, and always with perfect success. The patient must be told to *swallow* the liquid, not gargle. Application with a brush will do no good. He should swallow the fluid slowly, as if it were difficult to get it down, and must on no account wash out his mouth or gargle."—*Edinburgh Med. Journal*, Jan. 1889.

Puerperal Mortality.—During recent years the mortality attending childbirth has shown a steady decrease, so that the maternal death-rate has fallen from the ten to fifteen per cent. of some years ago, to almost *nil* at the present day. Puerperal septicæmia, once the dread of the practitioner, is now gradually but surely being stamped out, and in the not distant future we may hope to see the mortality from this class of case reckoned, not by the fraction per cent., but by the fraction per thousand. The introduction of antiseptics into midwifery was indeed a very great stride, but it is to the more effectual carrying out of this system, and to its more perfect elaboration, that further and more brilliant results are to be looked for in the future. Epidemic outbursts of puerperal septicæmia have been greatly diminished, owing to improved hygienic surroundings and the introduction of antiseptics; whilst, if septicæmia should occur, our improved methods of treatment render the disease more tractable and less to be feared.—*British Medical Journal*, December 29, 1888.

Antiseptic Pastilles.—DR. ROTTER, of Munich, after numerous careful investigations to decide which antiseptic would be best adapted to the disinfection of the hands, has concluded that the following compound answers all purposes:

℞.—Sublimate		⅞ grain.
Carbolic acid		30 grains.
Chloride of zinc	āā	77 "
Sulpho-carbolate of zinc		
Boracic acid		45 grains.
Salicylic acid		9 "
Thymol		2 "
Citric acid		2 drops.

This compound dissolved in two pints of water has the same antiseptic properties as 1 : 1000 sublimate solution, which properties it even retains if the sublimate and carbolic acid are omitted.

The author has succeeded in converting this compound into tablets, each containing the quantity and amount of the ingredients mentioned. They are easily soluble and would seem to answer all purposes, the author having made use of them in twenty-seven surgical and twenty-six gynecological cases with the most gratifying results.—*Münchener med. Wochenschrift*, December 18, 1888.

Rhus Aromatica in Atony of the Bladder.—Rhus aromatica, the fragrant sumach of the United States, is recommended by several French physicians as a valuable remedy in cases of incontinence of urine, and in atonic conditions of the bladder and its sphincter. Children from two to six years old may take ten drops night and morning, and older children fifteen drops for a dose. The tonic effect of the medicine does not always persist, but the trouble is liable to return when its use is suspended. It may be given in simple elixir.—*American Druggist*, January, 1889.

Treatment of Sycosis.—DR. GEORGE THOMAS JACKSON, in a paper on this subject read before the New York Dermatological Society, November 27, 1888, concluded that from a number of cases which came under his observation, the following treatment yielded the most satisfactory results:

In acute cases in which there is much pustulation, epilate or curette, and apply boric acid ointment, or Lassar's paste with salycilic acid. Give one-tenth of a grain of calcium sulphide in fresh tablet triturates every one or

two hours. If an acute outbreak of pustules occurs under it, stop it until a subsidence of the eruption takes place, and then begin again.

In subacute cases in which there is not so much pustulation, but more redness, and the disease is more patchy, epilate or curette and use Bronson's ointment, or one of sulphur or tar, or other mild stimulant. Or use soap frictions, followed by protective ointments.

In chronic cases, epilate or curette, or apply a solution of caustic potash carefully to diseased parts. Locally, employ strong ointments or solutions of tar, provided caustic potash has not been used. If caustic potash has been used, then apply a simple soothing dressing. The use of tar in alcohol, as proposed by Pick, of Prague, has of late given brilliant results in Jackson's hands in some cases of chronic eczema, and in the last few days has greatly benefited one of the cases here reported, one which had shown itself to be very obstinate. Soap frictions are also valuable at this time. As chronic and subacute cases may take on acute forms under stimulating treatment, we must be prepared at any moment to apply more soothing methods of cure according to indication.

For the best effect from our local treatment we must insist upon our remedies being kept constantly applied during day and night. To the same end the patient is to be advised to shave himself about twice a week. This is not absolutely necessary, but facilitates the action of the application upon the diseased skin. If a rhinitis be present, appropriate remedies must be used for that.

While treating the skin affection we must not forget the man whom the skin clothes. We must address ourselves to the task of regulating the diet and general hygiene of the patient, and give medicine, if needs must, upon the same principle as we would if the patient came to us not for his sycosis, but on account of his poor general condition.—*Journal of Cutaneous and Genito-Urinary Diseases*, January, 1889.

Mercurial Inunction in Typhoid Fever.—Three years ago a short account was given of a method of treating typhoid fever which DR. KALB, of Thalmassing, had found very successful in one hundred cases in which he had tried it, in eighty per cent. of the cases fever entirely disappeared within ten days. The treatment consisted of rubbing one gramme (fifteen grains) of mercury ointment into the abdomen on the first day, into the inner aspect of one thigh on the second day, and on the third day into the other thigh. The course was repeated during the three following days. Dr. Kalb also gave alcohol methodically, and a few calomel and opium pills on the first day. Dr. Felix Bartlett has published a short paper in the *Australasian Medical Gazette* (November, 1888) in which he confirms Dr. Kalb's statement. He found that the temperature fell to normal in two or three days, and that in five or six days from the commencement of the treatment all other symptoms had disappeared. Both Dr. Kalb and Dr. Bartlett agree also in stating that the treatment by inunction is only of use when commenced before the ninth or tenth day of the disease, and as this is a period when the symptoms are not very distinctive it is possible that, in some instances, the cases submitted to this treatment were only febricula.

The history of one family given by Dr. Bartlett is of special value as affording evidence generally so difficult to obtain on this head. He says: "In one house a child of four first fell ill. She was not seen by me until the end of the second week. She had a very severe attack, and narrowly escaped with her life. Whilst I was attending upon this case the mother, who was nursing the child, and also two elder children who were in the house, showed undoubted symptoms of enteric fever, with considerable rise of temperature. All three were put under this treatment at once. The symptoms rapidly disappeared, and none of them was in bed more than five or six days. The father next fell ill with precisely the same symptoms, but having to go away on urgent business, refused all treatment. He, however, returned in a few days with the symptoms fully developed, and he ultimately died of the disease. Two servant girls in the house also suffered, but neither said anything about her symptoms until in the third week; one had an ordinary attack, the other a severe one, but both ultimately recovered." In another house, where also the first sufferer was a child, "the mother and the servant both developed decided symptoms, but, being put under treatment, were convalescent in a few days." Dr. Kalb was more cautious in speaking of the early complete recovery of his patients; he found that the spleen remained enlarged for about a fortnight after the fall of temperature, and advised that the patients should be kept under strict observation during this time for fear of a relapse.

It may be useful to recall here that calomel has been lately used, especially in Germany, in the treatment of typhoid fever. Liebermeister has given some striking statistics on this point. He gives the results of 839 cases; 239 were treated with iodine, 223 with calomel, and 377 with neither, the rest of the treatment being exactly alike in all, and consisting in the employment of a partial antipyretic method. Of the cases treated with iodine, 35, or 14.6 per cent. died; of those treated with calomel, 26, or 11.7 per cent. died; while of those non-specifically treated, 69, or 18.3 per cent., died.—*British Medical Journal*, January 5, 1889.

Borax in the Treatment of Diphtheria.—DR. L. NOËL, of Noyers-Saint-Martin, has had considerable success with the following treatment practised by him for the last four years.

Starting with the belief that diphtheria is not a local but a constitutional disease, he sought a remedy which could be introduced into the system in quantities large enough, so to speak, to "crowd out," and not merely modify the action of the poison. The author thus selected borax from all other antiseptics, as bearing administration in large doses without danger to the patients.

In epidemics of diphtheria, the author administered nothing but borax, with but three deaths out of sixty cases thus treated.

The author claims that this agent produces a rapid and abundant salivation; and, in being eliminated by the salivary and muciparous glands of the throat, it softens and detaches the false membranes.

The dose is from 8 to 15 grains in an infant below one year of age; of from 15 to 22 grains for two to five years; of 30 grains for five to ten years; and from 45 to 75 grains for adults, according to the strength of the patient and the severity of the disease. No better results were obtained from 200 grains or over than were obtained

from 60 to 75 grains. The doses are to be equally divided, and given hourly, except during sleep.

In order not to disgust the patient, the correctives in which this salt is given must be frequently changed, as the administration of this medicament must be continued for some time after all symptoms of the disease have passed off, the author having administered it to two patients uninterruptedly for four and six weeks.—*Revue Thérapeutique*, December 15, 1888.

The Obstetric Therapeutics of 1888.—The effect of ergot in involution of the uterus has been studied by Herman, and the results appear to us to demonstrate that the continued use of ergot during the process of involution of the uterus is to be deprecated. Blanc, a French physician, from the observations of the use of this drug in two hundred cases of parturition, arrived at practically no conclusion; if anything, his investigations led him to believe that involution was retarded. Pilocarpine in labor receives attention, but the conclusions arrived at and the deductions drawn are hardly such as to encourage the use of the drug in any of the stages of labor. Cocaine, for the relief of pain in the earlier stages of labor, has been tried, but does not meet with general approbation; and the same may be said of antipyrin, though we are inclined to believe that further trial of this last drug will prove it to be of some service. Silicofluoride of soda, or "salufer," as an antiseptic for intrauterine or vaginal douches, is highly spoken of, and said to be most efficient. It has the advantage of being "a nearly perfect antiseptic agent," and, unlike the perchloride of mercury solutions, it does not roughen the hands, spoil instruments, or set up poisonous symptoms; while, at the same time, it is a very powerful germicide, and, according to Mayo Robson, a solution of "0.61 per cent. possesses greater antiseptic power for animal tissue than a one in five hundred perchloride of mercury solution."—*British Medical Journal*, December 29, 1888.

Pneumotomy for Pulmonary Abscess.—PROFESSOR F. M. OPENSOVSKY, of Dorpat, relates in the *Vratch*, No. 38, 1888, a strikingly successful case of pneumotomy for an enormous abscess of the right lung, with gangrene, in a man aged thirty. The patient had enjoyed excellent health up to the middle of April, 1886, when, in consequence of exposure, he caught severe pleuro-pneumonia, which ended in suppuration. Three weeks after the onset of the illness he expectorated a tumblerful of offensive pus. The suppuration steadily progressed, being accompanied by violent cough, hectic fever, and emaciation. About the middle of September signs of pulmonary gangrene appeared. Pneumotomy was performed by Professor W. Koch, on September 19th. The patient being slightly under the influence of chloroform, two pieces, each ten centimetres long, were excised from the fifth and seventh ribs, between the anterior and posterior axillary lines. The pleura having been found firmly adherent, a thermo-cautery was plunged into the pulmonary tissue, striking the abscess-cavity at a depth of two or three centimetres; this was followed by cough and the expulsion of a large amount of fetid greenish pus. On placing the man on his right side a tumblerful of pus immediately escaped. The cavity was so large as to allow Professor Opensovsky to introduce his whole hand and freely move it about, searching for the bronchial opening. Having removed with the fingers several pieces of sloughing tissue, the operator enlarged the bronchus with the thermo-cautery, and then freely cauterized the whole gangrenous focus, afterward washing out the cavity with a weak solution of permanganate of potash. In conclusion, a fenestrated drainage-tube was inserted, and an antiseptic dressing applied. The irrigations were repeated twice daily for the first ten days, and only once a day up to October 26th, when the drainage-tube was removed. The temperature became normal on the eighth day after the operation. In November the wound closed, and on December 8th the patient was discharged, practically well. On re-examination about a year and a half later, a shallow funnel-like depression was found at the site of the operation, with a slight spinal curvature with the concavity toward the right; but the man felt quite well, and was able to earn his living as a hospital porter.

According to Professor Opensovsky, this is about the twentieth case of pneumotomy for pulmonary abscess, and the fourth in which complete recovery has taken place without a fistula being left.—*British Medical Journal*, January 5, 1889.

Iodoform in Diphtheria.—In the Polish weekly *Gazeta Lekarska*, No. 36, 1888, DR. A. PULAWSKI, of Warsaw, details seventeen cases of diphtheria, mostly of a severe kind, rapidly cured by the local use of powdered iodoform, in quantities varying from five to ten grains twice or thrice daily. The drug was applied by means of a brush or an insufflator. According to Dr. Pulawski, iodoform acts as an antiseptic, and represents, generally, the best anti-diphtherial means of all known. The main advantages are said to consist in, 1st, its being absorbed but gradually; 2d, in its application being easy and simple; and 3d, in its manipulation (powdering, insufflation) being free from such dangers as wounding the affected mucous membranes.—*St. Louis Med. and Surg. Journal*, Jan. 1889.

Remarkable Tolerance of Nitro-glycerin.—DR. DAVID D. STEWART (*Polyclinic*, December, 1888) reports a case of chronic parenchymatous nephritis, in a male aged twenty-six, in which tolerance to nitro-glycerin was so rapidly acquired that, a few months after its administration was begun, no dose, short of one which to prescribe seemed hazardous, exerted any appreciable influence on the vascular system. When the case first came under observation there were present slight cardiac hypertrophy with arterial fibrosis; dropsy, scanty urine of light gravity, containing an abundance of albumin and casts. In addition to other remedies, one minim of a one per cent. solution of nitro-glycerin, four times daily, was prescribed. To maintain a constant effect, this dose was directed to be gradually and systematically increased. In less than seven months the patient was taking fifty minims of a ten per cent. solution, four times daily—an equivalent of twenty minims of pure nitro-glycerin in the twenty-four hours, with no more appreciable subjective or objective effect than was originally produced by the initial dose of one minim of the one per cent. solution. His condition has steadily improved. Dropsy has disappeared. The urine has become normal in amount. Casts cannot be found in any of the recent specimens examined, and the albumin has decreased from many grammes to but one per litre.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JANUARY 26, 1889.

THE PRACTICE OF OBSTETRICAL ANTISEPSIS BY NURSES.

THE theory of antisepsis in obstetrics has had sufficient trial to give evidence of its practical value, and it is at present more a question of the mode of practising antisepsis than of the value of the method. The education of nurses in America has reached the point where a considerable number of competent women, practically familiar with surgical and obstetrical antisepsis, are graduated from hospital schools yearly. There remains, however, a considerable number of untrained nurses, not familiar with the use of antiseptics, for whose guidance simple, explicit rules are needed. The problem of the application of antiseptic treatment outside of hospitals awaits a complete solution, for nurses perfectly competent when possessed of the apparatus and solutions furnished in hospitals may be puzzled in attempting antiseptic treatment in dwellings.

The rules recently added to the *Manual of Midwifery for Prussian Midwives*, which were published in this country in THE MEDICAL NEWS of last week (page 83), and recent writings and discussions by Ahlfeld, Valenta, and others, afford information of practical value. Of primary importance for nurse, as well as physician, is strict personal cleanliness; the toilet of the hands must be exact, the ordinary clothing clean and covered by a large clean apron. The forearms must be bare and cleansed with the hands; the nurse must carry toilet articles used by her only. German authorities do not, at present, entrust bichloride of mercury to midwives and nurses; fluid carbolic acid is provided, with a measuring glass and glass irrigator of marked capacity, in which definite solutions are prepared; explicit directions for making solutions and mixing carbolized oil or glycerine are given, every precaution being taken against the possibility of injuring a patient by undissolved acid. The apparatus needed by the nurse is very simple, an irrigator, elastic tubing, suitable canulæ and catheters, with absorbent cotton or jute. The instructions given may be stated in the three simple propositions: strict personal cleanliness; strict aseptic cleanliness for the patient and all touching her; non-interference without positive indications. The last refers especially to vaginal injections, which must never be given without the doctor's order, or the existence of unmistakable indications, which are clearly defined.

The use of bichloride of mercury, so common in American hospitals, cannot be criticised when in the hands of a nurse of known intelligence and experience; in less skilful hands the usage of the German Government is to be commended. Dispensary physicians, and those who assign cases to medical students, may profit by these regulations in instructing those who care for the poor after confinement; in the absence of midwives instructed by the government, such attention to the details of obstetric practice is especially incumbent on practitioners. Dispensaries might easily furnish standard solutions of antiseptics and sterilized cotton or jute, to be used instead of sponges. There is no field of practice in which meddlesome ignorance can do such great harm as in obstetrical practice, and no work in which the faithful observance of the simple axioms of science can obtain such excellent results.

THE BACILLUS OF YELLOW FEVER.

IN another column we have the pleasure of laying before our readers a paper, which was read by DR. PAUL GIBIER, last week, before the New York Academy of Medicine, describing the results of his researches during the late epidemic of yellow fever in Florida, which were prosecuted under commission from the French Government.

Dr. Gibier found in the intestine in one case the same bacillus which he saw in several cases of yellow fever in Havana in the winter of 1887–8, and which he believes to be the cause of the disease. This bacillus presents many points of resemblance to the

comma bacillus of cholera. He holds that the reason why this bacillus is not found in every case of the disease is because when a culture medium becomes saturated with a microörganism, its growth stops and another microbe then flourishes in the transformed medium, and the first disappears. Therefore, his microbe is likely to be found only in the early stage of the disease, and in the alkaline intestinal contents. A moist heat of 140° F. destroys the bacillus in a few minutes, and desiccation proves fatal to it within twenty-four hours. This last observation, in Dr. Gibier's opinion, explains the immunity of inland districts—the comparative dryness of the air destroying the bacillus.

This same bacillus, we believe, has also been isolated and carefully studied by Dr. Sternberg, who has reached a very different conclusion as to its etiological relation to yellow fever, and in his latest published utterance on the subject (*Transactions of the Association of American Physicians*, vol. iii., 1888) he briefly states his opinion that the specific agent of yellow fever has not yet been demonstrated.

In accordance with the view of Dr. Gibier, yellow fever is an intestinal infection, which must be treated from the onset by evacuants and disinfectants.

STATES MAY REGULATE MEDICAL PRACTICE.

AN interesting decision has been rendered by the Supreme Court of the United States, supporting the right, claimed by the State Board of Health of West Virginia, to make rules for the regulation of the practice of medicine. The statutes of that State enact that every practitioner must qualify himself for legal practice by obtaining from the Board a certificate that he is a graduate of a reputable medical college, or has been ten years in the State engaged in practice, or that he has passed a satisfactory examination before the Board. A practitioner, named F. M. Dent, having been convicted of illegal practice, carried the case up to the State Court of Appeals, and thence to the United States Supreme Court, asserting that the law was unconstitutional, inasmuch as it deprived him of liberty and property without due process of law.

The decision of the Supreme Court says: "The power of the State to provide for the general welfare of its people authorizes it to prescribe all such regulations as may be necessary to secure the people against the consequences of ignorance and incapacity as well as of deception and fraud. One means to secure this end is the method adopted by the State of West Virginia. If the means adopted are appropriate to the calling or profession, and obtainable by reasonable study or application, no objection to their validity can be raised."

If it is the right of the State under this weighty and memorable decision, to protect its citizens from pretenders and quacks, the duty so to protect them must be found by all diligent State Boards of Health to follow sharply thereafter. This duty to repress ignorant or fraudulent practice does not, of necessity, inhere in a Board of Health—in England, for example, it rests with the General Council of Medical Education and Registration—but it has been found expedient in this country to make the State Board the means for the correction of this form of abuse. In two States, at least, Illinois and California, a considerable improvement in medical practice has been accomplished, and we expect that West Virginia will presently report that her ranks have been purified from the worst of her quackish and ignorant impostors.

WE are gratified to chronicle that the Governor of Florida has called upon the Legislature of that State to convene in extraordinary session for the purpose of establishing a State Board of Health and for other sanitary measures. This is a most important step, and has been taken none too soon, for the Legislature will not meet until February 5th, and a considerable time must, of necessity, elapse before the ways and means can be agreed upon and the sanitary machinery be set in motion. It is to be hoped that the law-makers will be as prompt as possible in the adoption of a liberal and efficient charter for this new Board, upon which great responsibilities will rest.

DR. JOSEPH Y. PORTER, surgeon in charge of the Government relief measures, in the early part of the week sent the following official announcement of the completion of disinfection in Jacksonville to Surgeon-General Hamilton in Washington:

"The work of disinfection and destruction of infected bedding is practically finished in this city. It is perfectly safe for any one to visit Jacksonville who may wish to, as the work has been as thorough and efficient as human agency could make it. It speaks for itself that Jacksonville is perfectly clean. Please announce this through the public press, so that the timid may have their fears removed, and that confidence in the city may be restored."

On January 21st, the Auxiliary Sanitary Association tendered Dr. Porter resolutions expressing appreciation of the work done by him at Jacksonville during the past four months, and also presented him with a very handsome gold repeater watch and chain as a souvenir of his stay in Jacksonville. As all his sanitary work is now completed, Dr. Porter has left for Key West, his home.

THE Surgeon-General of the Army, in his report to the Secretary of War, recommends that authority be granted by Congress for the publication of a Catalogue of the Army Medical Museum.

DR. LANDON CARTER GRAY has been elected President of the New York Society of Medical Jurisprudence, and Chairman of the Neurological Section of the New York Academy of Medicine.

DR. W. W. KEEN has been elected President of the Philadelphia County Medical Society.

The Lancet announces that it has founded "*The Lancet* Medical Fund," the object of which is to afford immediate pecuniary assistance in emergencies to medical men, or, in case of the death of a medical man, to his widow or orphans or dependent relatives. The Almoners of the Fund are to be the President of the Royal College of Physicians, the President of the Royal College of Surgeons, the President of the General Medical Council, and the two proprietors of *The Lancet*. The latter will generously place at the disposal of the Almoners a sum of at least $1500 a year, which will be administered free of cost, and they do this to express their sense of the generous support which the profession has accorded to *The Lancet* during the sixty-six years of its publication.

THE Trustees of the Philadelphia Polyclinic and College for Graduates in Medicine have founded a chair of Diseases of the Mind and Nervous System, and have elected Dr. S. Weir Mitchell to the professorship.

The Trustees have purchased a large property on Lombard Street, above Eighteenth, for $25,500, which will be adapted to the uses of the institution.

DR. WILLIAM OSLER, Professor of Clinical Medicine in the University of Pennsylvania, will deliver the second annual address before the Society of the Alumni of the Bellevue Hospital, on Wednesday evening, April 3d, at the Hall of the New York Academy of Medicine.

THE Governor of Illinois, in his annual message, sent in to the General Assembly last week, pays the following just tribute to the State Board of Health: "The wise and intelligent policy of the Board on the subject of quarantine has been of great value to the material interests, not only of Illinois, but of the whole Mississippi Valley. While vigilantly guarding against the introduction and spread of the dangerous, contagious, and infectious diseases, it secures the least interference with commerce and travel, and so averts unfounded panics and prevents loss and interruption of business and industry. During the past few months a striking illustration of the value of this policy was afforded by the action of the worthy Secretary of the Board, who refused to sanction any expenditure of money from the public treasury in the maintenance of quarantine restrictions, which his wide and varied experience and scientific knowledge enabled him to pronounce unnecessary for the State. His firmness in this instance alone prevented the loss of thousands of dollars, besides great inconvenience to travellers and vexatious interference with business; and the example thus set materially helped to check the ruinous and needless quarantine enforced in other States."

LONDON maintains its position as the most healthful of the large capitals of the world. The health-rate of that city in 1888 was 18.5 per thousand, the lowest that it has yet recorded. The *Lancet* of January 5th points out, at the same time, a possibility that the official estimate of the city's population may be too high, since it is now eight years ago that the last census was taken; the estimate for the middle of 1888 being placed at 4,282,-921. The birth-rate, 30.7 per thousand, is also the lowest hitherto registered. Zymotic deaths were, as a rule, lower than in recent years; the only exception being those by diphtheria, which were never higher than in 1888. Diarrhœal causes had an unprecedentedly low rate, owing to the cold and wet summer season of last year.

AT Vienna a beginning has been made of a promising museum of specimens illustrative of medico-legal questions. About 1400 specimens have been gathered, chiefly by Professor Hofman and his assistants, and have been given a place at the General

Hospital, along with other and older collections. Considerable space is given to specimens relating to sexual jurisprudence, the production of abortion, homicide, suicide, the effect of poisons, of burns, the lodgement of foreign bodies in the respiratory passages, the identification of the dead body.

SOCIETY PROCEEDINGS.

MONTREAL MEDICO-CHIRURGICAL SOCIETY.

Stated Meeting, January 11, 1889.

THE PRESIDENT, WM. GARDNER, M.D., IN THE CHAIR.

DR. JAMES BELL read a paper on

THE CAUSE AND PREVENTION OF URETHRAL FEVER.

After shortly describing the various theories held as to the cause of this fever, he said that every medical man was familiar with a certain form of constitutional disturbance which follows instrumental or operative interference within the urethra. Preëxisting disease of the kidneys, ureters, or bladder, sepsis, etc., may explain some of the cases, but there still remained behind a large class of cases occurring in male patients of all ages, in which operative or instrumental interference will be followed by a train of symptoms to which have been given many names, such as urethral fever, urine fever, catheter fever, etc. The symptoms occur in four different forms:

(1) Shock, collapse, and death within a few hours after operation, with or without chill or fever, and with partial or complete suppression of urine.

(2) A severe chill with high fever occurring a few hours after operation, and usually following the first act of micturition. Profuse sweating and prostration follow, but the whole disturbance lasts from only a few hours to two or three days.

(3) Recurrent chills and high fever coming on at irregular intervals and lasting perhaps for weeks and months.

(4) A moderate fever with slight chills or chilly feelings, accompanied by great depression, low muttering delirium or semi-coma; patient gradually passing into a typhoid condition, and dying in two or three weeks. Such cases occur in old men with large prostates, especially in those in whom frequent catheterization has resulted in the formation of false passages.

The various symptoms called urethral fever have been attributed to—

(1) Septicæmia.

(2) Reflex nervous phenomena.

(3) Uræmia.

Dr. Bell went on to say that in December, 1883, Sir Anthew Clarke read a paper, before the Medical Society of London, on "Catheter Fever," which called forth a spirited discussion, in which all the leading genito-urinary surgeons took part. No definite conclusions, however, were arrived at.

The reader of the paper stated that a very casual investigation of the subject shows the utter inadequacy of any of the theories mentioned above. It differs entirely from pyæmia and septicæmia in its symptoms and in the absence of gross lesions; nervous disturbance in no other cases causes such symptoms, and it corresponds to no known form of uræmia.

The discovery of the animal alkaloids, known as ptomaines and leucomaines, and the experiments of Dr. Burchard, of Paris, from 1882–6, upon the toxicity of the alkaloidal substance found in normal urine, seem to give the key to a rational explanation of the origin of urine fever. There can now be hardly any doubt that the disease is due to the absorption of the products of decomposed or decomposing urine from cut, lacerated, or abraded portions of the urethra. It is not a septic process but a form of poisoning closely allied to uræmia and due to the absorption of a toxic alkaloid, produced by or during the decomposition of the urine. The clinical facts in support of this are very strong, and were tabulated by Dr. Bell as follows:

(1) Urine fever is unknown after perineal lithotomy, external and internal urethrotomy in the pendulous urethra, and is far less frequent when the urethra is wounded in its floor.

(2) When, after internal urethrotomy, the urethra and bladder have been carefully washed out with an antiseptic solution, urine fever does not occur until some hours after urine has been passed over the wounded urethral surface, and is then of a mild type and free from danger.

(3) Operations upon the female genitals, which wound or injure the urethra, are not followed by urine fever.

(4) Mr. Reginald Harrison, of Liverpool, has shown by a number of operations that when the bladder is drained by a perineal wound after internal urethrotomy that urine fever never occurs, and he attributes its origin to the absorption of the products of the decomposing urine in wounds of the urethral mucous membrane.

The reader of the paper said that it was primarily with the object of adding his experience in support of this important observation, and his testimony in favor of the combined operation that he brought this subject forward. He related the history of five cases operated on by the combined method during the last few months. In these five cases he drained the bladder by the perineum after having divided the stricture internally, after Mr. Harrison's method. All five cases selected were specially intractable strictures due to traumatism, etc., and situated in the deep urethra, and in several cases the strictures were multiple. All these cases recovered from the operation without a bad symptom, no rigors or fever. In contrast to the result obtained in unfavorable cases, Dr. Bell related six cases of simple stricture which he had treated by internal urethrotomy alone; in four of these urethral fever supervened—in each case after urination.

Dr. Bell drew the following conclusions:

(1) That urine fever is a consequence of the lodgement and decomposition of urine in contact with a wounded urethra, the inference being that the absorption of the product of decomposition which takes place from wounded surfaces, and which could not occur through the normal urethral mucous membrane, is the direct cause of this condition.

(2) Urine fever is *absolutely preventable*, either by providing a dependent drain, so that urine could not lie in contact with the wounded urethral surface long enough

to decompose, or by preventing the decomposition of the urine by drugs or antiseptic injections.

(3) That a perineal cystotomy is a simple and easily performed operation, which does not materially add to the risks attending urethrotomy, and is not followed by unpleasant consequences if the drainage tube be not retained too long.

(4) That decomposition of urine can be delayed for a considerable time by thorough cleansing of the urethra and bladder, and by injections with antiseptic solutions after operation. This, with the precaution on the part of the patient of abstaining from passing urine for as long as possible, will greatly lessen the frequency of urethral fever.

(5) Quinine, aconite, and other drugs may be of use when urine fever has occurred, but they are powerless in most cases to avert it.

(6) Patients with enlarged prostate, who have suffered from laceration of the deep urethra, should be treated by perineal cystotomy at once in order to avert urine fever, which is likely to occur as soon as the patient is able to evacuate urine without a catheter.

DR. RODDICK, in the discussion which followed the reading of the paper, said that many of the cases of urethral fever which formerly were so common were no doubt due to sepsis—sufficient attention was not paid to the cleanliness of instruments. This would, however, not explain all the cases. He agreed with the reader of the paper in thinking that external urethrotomy was the proper operation in cases of severe stricture, but he would not complicate it with an internal urethrotomy. The external operation was not such a simple one as Dr. Bell said it was, he had seen death follow the operation and occasionally a fistula persists. Dr. Roddick had great faith in the administration of quinine and aconite in cases of operation on the urethra and he was convinced that they often prevented the occurrence of urethral fever; he related the case of a man who had been operated on several times by internal urethrotomy. When quinine was given there was no urethral fever, but when its administration was omitted severe fever followed the operation.

DR. SHEPHERD said that he entirely agreed with the views concerning the origin of many cases ot urethral fever, advanced by the reader of the paper; these views had been ably discussed and illustrated by Mr. Reginald Harrison, of Liverpool, in the Lettsomian Lectures of last year, and in addition to the evidence offered by Dr. Bell he might add the fact that in cases of enlarged prostate with retention where the patient had been subjected to prolonged and ineffectual attempts at relief by catheterism, and where there was injury to the urethra, no urine fever followed if the urine was drawn off by aspiration above the pubes. He thought, however, that a distinction should be drawn between urethral or urine fever and the so-called catheter fever which followed the commencement of catheter life in old people with large prostate and which often terminated fatally at the end of two or three weeks; here the probable source of the mischief was in the kidneys. Even in these cases rest in bed during the first week and catheterization under ether averted the attack of catheter fever.

Dr. Bell had referred to the internal administration of drugs, and seemed to think that they had no power to prevent an attack of urine fever. This he could not agree with. He had frequently seen urine fever averted by the administration of drugs, such as quinine, etc., before or immediately after the catheterization or operation. Some held that the individuals thus influenced by quinine had been previously the subjects of malaria, but the fact remained that a full dose of opium or quinine frequently prevented the onset of the fever. In illustration of this a case was cited where on passing a catheter for stricture, when quinine was omitted urine fever invariably followed. Dr. Palmer, of Louisville, Ky., advocates the administration of boracic acid for some days before internal urethrotomy, to sterilize the urine. In forty cases operated on, only one had urethral fever, and in this case boracic acid had been omitted. Dr. Shepherd had no doubt that by giving drugs such as quinine, boracic acid, etc., which were largely eliminated by the kidneys, the urine could be sterilized, and urethral fever averted. He himself was in the habit of trusting to opium and quinine.

DR. T. WESLEY MILLS said that all forms of urine fever could not be reduced to one type. No doubt, chills and fever frequently follow catheterization or operation, but the occurrence of ptomaines in the urine will not altogether explain this, and facts have been adduced to prove this. Irritation will explain some cases; at least this may explain the beginning of an attack, which is afterward aggravated by ptomaines. The normal depends on ingoing influences, and the abnormal on derangement of these. Has opium, quinine, or even whiskey been given before the operation? These lessen nervous irritation. He thought the views advanced too narrow, and broader grounds must be taken.

DR. STEWART asked if urethral fever was not caused by the mere introduction of an instrument, without abrasion.

DR. RUTTAN could not quite agree with Dr. Mills that the group of symptoms known under the name of urethral fever were of nervous origin; he thought that the ptomaines theory was the strongest. The toxic action of normal urine has been long established, and the experiments of Burchard and Gautier go to establish the development of ptomaines in fermenting urine. It is not usually understood why, for all putrefactive alkaloids so far found in urine have the effect of depressing the system, lowering the blood pressure, pulse, and temperature.

The phenomena observed in urethral fever are those of increased metabolism and high temperature; these, then, must be due to some, as yet unknown, constituents of the urine. He could not see why it was necessary to suppose that the urine underwent decomposition in contact with the raw surface of the wound. Gaucher, in some recent experiments, has shown that the extractives normally present in urine, such as creatin, creatinin, xanthin, etc., when introduced into the circulation in minute doses are capable of giving rise to serious systemic disturbance, and, if continued, of inducing an acute nephritis, anuria, and death. Now, as normal urine contains a number of leucomaines or physiological alkaloids of higher toxic powers than creatinin, their absorption might account for some of the phenomena observed. If urethral fever be not due to alkaloids, it is a curious coincidence that those drugs which are most in favor in the treatment of such cases are alkaloids, and many of them physiological antidotes to ptomaines

already worked out. Brieger's toxic neuridin is rendered almost innocuous by aconite, others are counteracted by morphia, atropia, and other drugs employed in urethral fever. The very argument adduced by Dr. Shepherd against urine fever being due to ptomaines is in favor of that theory, for rest in bed is the very treatment to prevent the formation of poisonous ptomaines, these being formed during exercise only. He could well imagine how useful boracic acid would be in such cases, for it is eliminated almost unchanged by the kidneys.

DR. GARDNER asked if the introduction of these alkaloids into the body was attended by high temperature.

DR. RUTTAN said there was no elevation of temperature when these were introduced, which was an argument against the ptomaine theory.

DR. LAFLEUR asked Dr. Bell if the shiver which sometimes accompanies the act of micturition should be looked upon as a form of urine fever, and if not, where were we to draw the line?

DR. BELL, in reply to Dr. Roddick, said he did not perform external urethrotomy, but merely opened the membranous urethra for purposes of drainage. If the tube was retained for only three or four days no fistula could possibly result. He thought the catheter fever of old men was different from the urine fever following operations on the urethra in apparently healthy men. He had treated the subject from a purely clinical standpoint, and had not specially considered its physiological or chemical bearings, and he said that what he regarded as essential to prevent urethral fever was, (1) to prevent the lodgement of urine in contact with a wound of the deep urethra, and (2) to prevent its decomposition in such a situation.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, January 3, 1889.

THE PRESIDENT, THOMAS M. DRYSDALE, M.D., IN THE CHAIR.

DR. C. P. NOBLE reported

A NEW METHOD OF DIAGNOSIS IN OBSCURE CASES OF ENTERO-VESICAL FISTULA.

He had been recently asked by Dr. C. M. Wilson to see a patient supposed to be suffering from a fistula. It was not his purpose to report the case in full. Briefly, the woman had what is called an ischio-rectal abscess, about five years before. Some time after this abscess discharged she stated that she began to pass wind and small pieces of fecal matter *per urethram*, at irregular intervals. No symptoms of bladder irritation existed. An extensive cicatrix following ulceration produced by a pessary, is present in the vagina. It extends along both sides of the vagina and across the posterior fornix (behind the cervix). In view of the absence of bladder irritation and the well-known haziness of the knowledge of anatomy possessed by the laity, it was thought likely that if the fistula did exist it was a recto-vaginal fistula. A careful examination under anæsthesia by touch and sight made by Drs. Wilson, Hawley, himself, and others, failed to demonstrate the existence of any fistula communicating with the vagina. But two conclusions could be drawn; either the woman was right or else she was a malingerer. The latter seemed probable from what was known of her.

It was suggested that a careful and extended study of the urine, made with the microscope, might determine the diagnosis—particles of vegetable fibre or seed of small fruits might be found. This plan involved much labor and time. It occurred to him that the hydrogen gas test would settle the matter quickly and positively and he suggested that it be employed. The recommendation was accepted and followed the next day. Dr. Wilson forced the gas into the rectum and lighted the gas at the end of a catheter introduced into the bladder. Dr. Noble was unable to be present at the time, but Dr. Wilson told him that no gurgling sound was heard (caused by the gas passing the ileo-cœcal valve), hence it seems plain that the communication exists between the bladder and the large intestine. Dr. Noble offered this as a new and valuable method of diagnosis in obscure cases of entero-vesical fistula: or a new application of Senn's hydrogen gas test.

NEW YORK NEUROLOGICAL ASSOCIATION.

Stated Meeting, January 8, 1889.

THE PRESIDENT, GEORGE W. JACOBY, M.D., IN THE CHAIR.

DR. GRAEME M. HAMMOND exhibited a male patient with

TRAUMATIC HYSTERIA.

He had been injured July 11, 1885, by falling upon a sharp-pointed iron rod one inch in diameter, which penetrated into the right submaxillary region about one and one-third inches from the median line. It passed in about four inches in a direction upward, backward, and inward. Dr. Philip Zenner, of Cincinnati, saw the patient a half hour subsequent to the accident, and has described his symptoms in the *Medical Record*. He was then suffering from paralysis of the right arm and leg, right side of the face, tongue, and palate. There was complete anæsthesia of the left side of the face, and loss of taste on the left side of the tongue and of smell in the left nostril. There was intense pain in the region supplied by the middle division of the fifth nerve. He consulted Dr. Hammond for the relief of this pain, and his advice was to excise the middle division of the nerve. The patient was sent by him to St. Luke's Hospital, where Dr. Robert Abbe operated November 16th. The nerve was excised almost to Meckel's ganglion. The next day the patient was again examined. The intense facial pain had disappeared, and the anæsthesia of the two other divisions of the fifth had also disappeared. The senses of smell and taste were restored, and the hemiplegia was markedly improved. At the present time, seven weeks after the operation, there has been no relapse. Dr. Hammond's conclusion was: that although a certain amount of organic lesion was undoubtedly present, yet the fact that so many symptoms were relieved by an operation which would not have affected them at all if they had been produced by a central lesion, showed conclusively that hysteria must be regarded as the sole cause of their production.

DR. C. L. DANA asked if the whole side of the tongue was affected, and was answered in the affirmative. He stated that he had seen the patient previously, and that

the gain in motor power since the operation was little, that there was still considerable loss of power and rigidity. There was no doubt that he had a genuine trauma at the base of the brain, and that he now has an organic lesion upon which some hysteria is superimposed.

DR. FREDERICK PETERSON did not think that a true ankle clonus, such as was obtained in this case, could be obtained in simple and pure hysteria. He had not met with true clonus in hysteria, but had frequently observed what Gowers describes as a spurious clonus, due to a half voluntary contraction of calf-muscles, and which Gowers considers characteristic of hysteria.

DR. B. SACHS believed that an actual clonus is observed in pure functional neuroses at times, and stated that such cases are cited by Oppenheim. He thought the marked hysterical element in this case and the rapid improvement made it possibly one of hysteria. He asked if there were any hysterical symptoms in the previous history of the case, and was answered in the negative.

DR. HAMMOND closed the discussion by saying he thought there was a real organic lesion also in the case, but that the anæsthesia, part of the hemiplegia, and the loss of taste and smell were hysterical.

DR. ISAAC OTT, of Easton, Pa., then read a paper upon the

THERMO-POLYPNŒIC CENTRE AND THERMOTAXIS,

the following being his conclusions from sixty experiments:

1. The thermo-polypnœic centre is situated in the gray matter about the third ventricle, at its anterior part.

2. This centre acts reflexly, so that when heat is thrown on the body the sensory impulses excited by the heat are conveyed to the polypnœic centre, which stirs up the respiratory centre to throw off heat. It stands between heat production on one side and heat dissipation on the other.

3. The fall of the number of respirations by the heat after the removal of the polypnœic centre is due to an excitation of fibres running in the vagi, which inhibit the respiratory centre.

4. The normal temperature of the body is not necessarily dependent upon the amount of heat produced or dissipated, for human calorimetry shows that the heat production varies, but that the temperature remains nearly the same. The relation of heat production to heat dissipation decides the temperature.

5. The cortical centres, the cruciate and Sylvian, are thermotaxic.

6. The four basal thermotaxic centres are situated as follows: one in the caudate nucleus, one in the gray matter beneath the caudate nucleus, another in the gray matter about the most anterior part of the third ventricle, and still another in the anterior inner end of the optic thalamus in the gray matter about the third ventricle.

7. These six thermotaxic centres are more circumscribed than Dr. Gerard, of Geneva, believes.

8. These six thermotaxic centres are neither thermo-inhibitory nor thermo-excitor, but thermotaxic; that is, they maintain the balance between heat production and heat dissipation, so that the temperature is kept normal.

9. In fever neither increased production nor increased dissipation nor high temperature are necessary, but fever is mainly a disease of thermotaxis, a disorder of the four basal thermotaxic centres. It is true in septic fever that in its initial stage heat production usually runs temporarily ahead of heat dissipation, but, exceptionally, both are immediately diminished.

10. Antipyretics do not necessarily inhibit or excite heat production or heat dissipation, but act upon the thermotaxic centres disordered by fever agents to restore order on normal thermotaxis. Prof. Chittenden's careful researches prove that in healthy hungry rabbits moderate doses of quinine exercise, at most, only a very slight depressing influence on body temperature, and have but a minimum effect upon the production of carbonic acid.

11. D'Arsonval's calorimeter for animals and men, as modified by the writer, is less liable to error than any other, as the agitator can be worked without opening the instrument or hardly disturbing the sawdust covering.

12. Human calorimetry shows that an adult after a full meal produces between 300 and 400 heat units per hour and not 110 calorics, as Helmholtz theoretically obtained.

DR. DANA did not question the truth of the author's statements. But what interpretation should we make of the six thermotaxic centres he had described? Can the bodily temperature be regulated without them at all? He referred to a case of his that he had recently published, in which, although there was no cerebrum, basal ganglia or cerebellum and only part of the pons, yet the temperature was normal. The facts of human pathology should be brought into harmony with these physiological experiments,

DR. OTT said it was difficult to understand the regulation of temperature in Dr. Dana's monster. Injuries to the corpus striatum disturb the temperature, but the other thermotaxic centres serve to regulate it.

DR. H. W. BERG then read a paper upon

ECLAMPSIA INFANTUM IN ITS RELATION TO FEVER,

in which he took the ground that febrile eclampsia calls into activity two sets of nerve-centres, the thermogenic and the convulsive. An alteration or lesion is produced in the thermogenic centre by excessive hyperæmia, anæmia or some minute structural change, causing a rise of temperature; secondarily, it affects the unstable convulsive centre in the medulla, especially in infants whose medullæ are in an exalted state of irritation. He thought it probable that the motor and thermic nerves are intermingled in the medulla, and thus an irritation of one results in irritation of the other. Thus fever produces convulsions in children, while the process may at times be reversed, as in the status epilepticus, where, after a period of convulsion, the temperature begins to rise, and, as Bourneville has pointed out, may reach an enormous height. He would treat febrile eclampsia, not with antispasmodics, but with antipyretic remedies; in other words, treat the cause of the convulsions. In this he had had gratifying success in the use of antipyrine and antifebrine together with cold or tepid sponging with equal parts of water and alcohol.

DR. OTT said that children, no doubt, have feeble thermogenic centres.

DR. WM. LESZYNSKY referred to a report of his some years ago of twenty or more cases of status epilepticus in which the rise in temperature did not accord with the statements of Bourneville. As to treatment, he thought simple sponging with alcohol and water sufficient, and

that the use of the wet pack or of antipyretics was objectionable.

DR. WEBER asked Dr. Ott if antipyrin and phenacetin act by assisting the system in the dissipation of heat.

DR. OTT stated that antipyrin probably decreases heat production and increases heat dissipation. The same would be true of phenacetin.

DR. WEBER thought dependence must not be placed upon antipyretics in severe cases of infantile eclampsia. Chloroform should be administered by inhalation or chloral injected per rectum. He had seen cold water injected with success.

DR. SACHS did not believe the relation of eclampsia and fever exactly that of effect and cause. Were convulsion due to high fever, it would be curious that in a fever preceded at its onset by convulsion, although the temperature continues high or increases, yet there are no subsequent convulsions. The fever in epilepsy was not due to excessive muscular exercise. A case of his with hystero-epilepsy had recently had as many as two hundred convulsions in twenty-four hours, but without any elevation of temperature.

DR. HARWOOD had treated eclampsia with chloroform and with the wet pack, and could heartily endorse the conclusions of Dr. Berg as to hydrotherapeusis.

DR. BERG, in closing the discussion, said he thought the instance cited by Dr. Sachs, of a fever ushered in by convulsion, yet without further eclampsic seizures, in spite of the continuance of the fever, did not carry as much weight with it as would at first appear, for Hughlings Jackson had pointed out that the convulsive centres could become so exhausted that the fits would not be repeated. He prefers the wet pack now to sponging, because refrigeration by the latter method is more rapid and more dangerous. He had seen pneumonia produced by sponging. The pack is less harmful.

NEWS ITEMS.

Quarantine Conference.—Dr. Jerome Cochran, Health Officer of the State of Alabama, has just issued the following circular letter.

Under a joint resolution of the General Assembly, the Governor of the State of Alabama has issued to the Governors of the States of Texas, Florida, Louisiana, Mississippi, South Carolina, North Carolina, Georgia, Tennessee, Kentucky, and Illinois, invitations to appoint delegates to a quarantine conference to be held in the city of Montgomery, beginning on Tuesday the 5th of March, next, and to continue for such number of days as the business in hand may render necessary.

About two weeks ago, Dr. C. P. Wilkinson, President of the Board of Health of the State of Louisiana, addressed a circular letter to the health authorities of these same States, suggesting a similar conference to be held in the city of Jacksonville, Florida. Dr. Cochran has been in correspondence with Dr. Wikinson, and the assemblage of the proposed conference in Montgomery meets with his approval.

The object of the conference cannot be easily overrated. It is to formulate in a way that will command the confidence of the general public and of the civil and sanitary authorities of the States concerned, and in the light of our latest experience and information, the principles and regulations which should govern our Southern quarantines, and at the same time to arrange such plans for harmony and concert of action as may seem practicable and desirable.

It is earnestly desired that all of the States included in the invitation shall be represented in the conference by full delegations of such of their citizens as are best fitted to discuss the theoretical and practical problems involved in the rational administration of quarantine in the South. The occasion ought to be made a very memorable one.

The conference proper will be composed exclusively of the duly accredited delegates of the States; but other persons interested in quarantine matters will be heartily welcomed to seats on the floor, and to take such part in the discussions as under the circumstances may seem expedient.

To facilitate the work of the conference, experts, believed to be specially qualified, will be requested to formulate in advance for discussion, a series of propositions covering the subjects of maritime quarantine, railroad quarantine, municipal quarantine, depopulation of infected towns, refugee camps, panics, stampedes, disinfection, health certificates, etc.

The assistance and coöperation of all who have had experience in the management of quarantines, and of all who have studied the progress of epidemics of yellow fever are desired, and suggestions through the mails will be thankfully received by Dr. Cochran, at Montgomery, Alabama.

The American Physiological Association.—A regular meeting of the American Physiological Association was held in the rooms of Jefferson Medical College, Philadelphia, on December 29, and at the University of Pennsylvania on December 31. A number of interesting communications were read. Professor Reichert recounted experiments showing that the anterior columns of the spinal cord possessed no irritability of their own, or that the power of excitability was confined to the posterior sensory columns. He also showed that the rate of transmission of a nervous impulse differed under different conditions. Dr. J. Warren described some recent experiments showing that a sensory impulse, such as the explosion of a torpedo, reinforced the knee-jerk, and drew the curve showing the variation of this reinforcement with the interval between the sensation and the knee-jerk. Dr. Donaldson showed specimens from which it could be seen that the effect of a long electrical stimulation was to decrease the size of the nuclei of ganglion-cells, and that the amount of this shrinkage was roughly proportional to the duration of the stimulation. Professor Martin in one paper gave the determinations of the minimal and maximal temperatures consistent with life that the blood supplied to an isolated heart could undergo, and in another showed that the variation in the amount of carbonic acid given off by a normal frog and one kept in the dark was due to the optical and not the psychic differences of the two states, because a frog depriv ed o its cerebral hemispheres acts in this respect just like a normal frog. All of these papers led to interesting discussions; and the discussion of Dr. Reichert's paper induced Dr. S. Weir Mitchell to place at the disposal of the Society two hundred dollars, to be devoted towards

aiding research upon the rate of nervous transmission, especially in man.

The Society was hospitably entertained, and found much pleasure in visiting the laboratories of the Jefferson Medical College and the University of Pennsylvania. The members of the Society were invited tc participate in the International Congress of Physiologists to be held at Basle in 1889.—*Science*, Jan. 4, 1889.

House-drainage.—Dr. J. S. Billings, in an interesting article in the January *Popular Science Monthly*, lays down the following principles of house-drainage:

1. Have no more fixtures and pipes than are really necessary, and have all the fixtures as close to the soil-pipes as possible. Do not put fixed wash-basins in any sleeping-room, nor any fixture in such a position that its outlet-pipe must run horizontally, or nearly so, beneath the floor for a distance of more than ten feet before it discharges into the soil-pipe.

2. Avoid, as far as possible, the placing of fixtures in the basement or cellar of the house. In a house properly constructed from a sanitary point of view, the basement or cellar should be entirely given up to heating and ventilating arrangements and to storage, and should not contain either kitchen, laundry, sinks, or closets. All the pipes for drainage, water, gas, etc., should be plainly visible and readily accessible on the ceilings or walls of this lower story, and this cannot be effected if kitchen-sinks or laundry-tubs are placed on the lowest floor.

3. Soil-pipes should be of cast-iron, of the kind known as extra heavy, and, for an ordinary dwelling-house, should be four inches in diameter, weighing about thirteen pounds per foot run. If the soil-pipe must be carried beneath the floor of the cellar or basement, it should be either bedded in cement or put in a brick trench with a removable cover. Every joint in a soil-pipe should be so made that it will not leak when the pipe is filled with water to a height of ten feet above the joint.

4. Provision must be made for the constant passage of a current of air through the soil-pipe from the bottom to the top, and it should have no dead ends. For this purpose it is necessary that the soil-pipe should pass up through the roof and be freely open at the top.

5. In order that a current of air shall pass through the soil-pipe, it most have an opening connected with the air below as well as above. Should this air which is to pass up through the soil-pipe be taken from the sewer, or from the air of the street? In other words, should there be a trap in the soil-pipe between the house and the sewer, with a fresh-air inlet between the trap and the house, or should the trap be omitted and the sewer be ventilated directly through the soil-pipes to the tops of the houses? The reply to this is, that where there are properly constructed self-cleansing sewers, having no cesspool connections, and the house connections of which are made under the control of the engineer having charge of the sewers, it is well to omit the trap between house and sewer, and let the latter ventilate directly through the soil-pipes; but exception should be made to this where the top of a soil-pipe would be on a level with or below the windows of inhabited rooms in a neighboring house. When the house-drains are connected with a cesspool, or with a sewer presenting the characters of a cesspool, it is safer to insert the trap; in which case there should always be a fresh-air opening between the trap and the house. If the pipes and fixtures in a house are properly arranged, and the joints are all tight, there is very little risk to the inhabitants of the house itself in having a direct connection with an ordinary sewer without a trap; the danger really being to the inhabitants of neighboring houses. On the other hand, if the trap between the sewer and the house be properly inserted, it creates no risk of danger or nuisance in the house to which it is applied, and costs little. The argument that it checks discharges from the house and tends to produce deposit in the horizontal part of the soil-pipes next to it on the house side, is unsound if this part of the pipe has a proper fall and the top of the trap is six inches below the pipe; for I have examined pipes which had been twelve years in use under such circumstances, and found no deposit worth speaking of. The question is of more importance taken in connection with the ventilation of sewers by street openings as affecting the comfort and health of the community generally than it is to the individual householder.

6. The incasing of fixtures in wood should be avoided as far as possible. The best bath-tubs and wash-basins are those in which the overflow is through a stand-pipe which is lifted to discharge the water, thus avoiding side or end overflows. The best closets are wash-out, short-hopper, or siphon-jet closets. Every closet should have its own cistern, and the flushing-pipe from the cistern should be not less than one and a half inches in diameter. Housemaids' sinks should have a flushing-rim and a separate cistern. Fixed laundry-tubs should never be made of wood. Urinals in a private house are usually an unnecessary nuisance; if put in, they must be cleansed frequently by rubbing. It is better that fixtures should be opposite windows than against outer walls, to avoid dark places beneath and around them, and to prevent danger of freezing the pipes.

7. To prevent the passage of soil-pipe and sewer gases, with their suspended microörganisms, through the fixtures into the house, some form of trap must be used, and this should always be placed as close as possible to the fixture which it is to guard. The best form of trap under all ordinary circumstances is a water-trap made by a bend in the pipe, forming what are known to all plumbers as S or half-S traps. Such a trap, so long as it preserves its water-seal, affords ample protection against both gases and bacteria, and, in ordinary dwelling houses, it is easily protected against the loss of its seal by evaportion or by siphonage. If a fixture remains unused for several months, its trap becomes unsealed by evaporation. In the trap to the outlet-pipe from an ordinary wash-basin this will occur in about two months if the trap is not ventilated, and in about two weeks if it is ventilated. As regards siphonage, the proper ventilation of the traps is a sufficient protection in all ordinary habitations of three or four stories. The ventilation of traps is not, however, solely for the prevention of siphonage; it is of equal if not greater importance to secure a current of air through all parts of the pipes so as to promote the constant oxidation and remove the slime which lines all pipes devoted to house-drainage. The immediate agents which produce this oxidation or slow burning of the organic matter which smears the interior of the pipes are those bacteria which are called aërobic, because they flourish best where there is plenty of oxygen. These are Nature's scavengers: the great majority

of them are not dangerous to health, but rather tend to destroy or starve out the really dangerous specific forms. They convert the soil-pipe slime into gases and soluble products, which products are washed away by the next flush of water; and they should be given a fair chance to do their work by giving them plenty of air. Where a closet is only three or four feet from the soil-pipe, this ventilation is not necessary for keeping the pipe clear; but it is more than ever necessary to prevent the siphonage. It is only under such circumstances that I would use a trap specially difficult to siphon and without ventilation; but such a trap should be cleansed every six months, for a trap which will not siphon will collect filth.

8. Whether the work be for construction or for repair, see that skilled workmen are employed upon it.

New York State Medical Society.—In addition to the papers already announced, the following have been promised for the meeting of the New York State Medical Society, beginning in Albany on Tuesday, February 5, 1889, at 10 A.M.

"The Treatment of the So-called Perityphlitic Abscesses," by Robert F. Weir.

"Basedow's Disease," by H. A. Hopkins.

"Cranial Measurements in Twenty Cases of Infantile Cerebral Hemiplegia," by Edward D. Fisher and Frederick Peterson.

"Cases Illustrating the Curative Effect of Convex Glasses in the Strabismus of Young Children."

"On Some of the Minor Types of Pneumonia," by T. E. Satterthwaite.

"The Practical Application of Acoustics to the Physical Signs of the Human Chest in Diagnosis," by J. R. Leaming.

"The Importance of the Early Recognition of Cancer of the Cervix Uteri," by Henry C. Coe.

"Office Photography with the Flash Light," by Henry G. Piffard.

"Inferior Dental Neurectomy," by J. H. Glass.

"Vaginal Hysterectomy," by James B. Hunter.

"Septic Poisoning in Early Life," by Henry D. Chapin.

"Amblyopia in Diabetes," by W. O. Moore.

Gentlemen who propose to discuss any of these papers will confer a favor by sending their names to Dr. Roosa, 20 East Thirtieth Street, New York, without delay.

A provisional programme will be sent to the members of the Society the last week in January.

Alum in Bread.—PROFESSOR J. W. MALLET, of the University of Virginia, has been pursuing an interesting course of investigations into the effects produced by the use of alum in bread, and has found that, as has long been assumed, it is injurious. In the United States the greater part of the baking powders sold, it has been found, are made with alum, the acid phosphate of calcium, bicarbonate of soda, and starch. The result of Professor Mallet's inquiry, as given in the *Pharmaceutical Journal*, has been to show that these powders give off very varying proportions of carbonic acid gas, and therefore different proportions have to be used for the same quantity of flour to produce the requisite porosity in bread. When moistened with water they yield small quantities of aluminium and calcium salts in a soluble form. Most of them leave, after use, the greater part of their alumina in the form of phosphate; but when acid phosphate of calcium is not used alumina is left. As the baking temperature in the interior of bread does not exceed 212° F., neither the water of combination of alumina or of its phosphate is removed from the residues of baking powder so used. However, in doses not very greatly exceeding such quantities as may be derived from bread as commonly used, Professor Mallet has found that hydrate and phosphate of alumina produced an inhibitory effect upon gastric digestion. He considers that this effect is probably a consequence of the union of alumina with the acid of the gastric juice, and at the same time of the precipitation of the organic peptic ferment in an insoluble condition like a kind of lake. A similar action may also be exerted by hydrate of alumina upon some of the organic matters of food. From the general nature of the results obtained, it is inferred that not only alum itself is injurious, but that likewise the residues resulting from its use in bread-making must be ranked as objectionable, and that the practice of adding alum should be studiously avoided when the object aimed at is to make wholesome bread.—*British Medical Journal*, January 5, 1889.

NOTES AND QUERIES.

ATROPHY OF THE SECRETING GLANDS OF THE STOMACH.

To the Editor of THE MEDICAL NEWS,

SIR: In THE MEDICAL NEWS of January 12th, I find this paragraph as the opening of the editorial article on "Atrophy of the Secreting Glands of the Stomach." It reads as follows: "The obscurity which always surrounds the diagnosis of atrophy of the gastric mucosa has been brought prominently into notice by the death of a well-known physician of this city, in whose case this diagnosis was accurately made—post-mortem," and it is further stated that "certainty in diagnosis has not yet been attained" by our present methods.

Permit me, from my own knowledge, to say of the case to which I suppose reference is made, that the diagnosis was accurately made during life, and that its correctness was confirmed post-mortem, but that the case was not one of gastric atrophy.

Of the nature of the disease it is not my province to speak—that belongs to another, and will, in due time, be made known. The disease was chiefly of the stomach, but not of the character inferred in the article. Yours, very truly,

MORRIS LONGSTRETH.

PHILADELPHIA, January 17, 1889.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING JANUARY 19, 1889.

DICKSON, A. H., *Passed Assistant Surgeon.*—Detached from the "Pensacola," and ordered to the "Atlanta."

OLCOTT, F. W., *Assistant Surgeon.*—Detached from the "Atlanta," and ordered to the "Vermont."

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL ARTICLES.

THE ETIOLOGY OF DIPHTHERIA.[1]

BY B. K. RACHFORD, M.D.,

DEMONSTRATOR OF BACTERIOLOGY IN THE MEDICAL COLLEGE OF OHIO, CINCINNATI.

FOR several years it has been the opinion of quite a number of eminent bacteriologists that diphtheria is a local disease and that the constitutional symptoms are produced by poisonous materials absorbed from the local lesion. It is the object of this paper to inquire into the truth or falsity of this opinion and to study certain other points relating to the etiology of this disease.

The present state of our knowledge derived from bacteriological investigations is as follows:

The most experienced bacteriologists have failed to find in the blood or tissues of animals any microorganisms which could possibly be etiologically related to diphtheria.

Every diphtheritic membrane contains many species of bacteria; these are chiefly those which normally inhabit the mouth, but septic bacteria are also almost always found.

Löffler found a streptococcus in the membrane which on injection into the ear of a rabbit produced a local disease erysipelatous in nature, and on injection into the blood of rabbits produced pyæmia. He also found a streptococcus in scarlatinous diphtheria which spread from the seat of infection through the entire body; this same coccus he found in other diseases which spread from a lesion of the mucous membrane.

To these organisms Löffler himself attaches no etiological significance. He describes, however, another bacterium which he believes is at least one of the causes of true diphtheria. It is a bacillus about the length of the tubercle bacillus, somewhat thicker, and found in the pseudo-membrane at the deepest part of the exudation, but never in the blood or tissues. Cultures on various nutrient media produced a white growth in two days. Guinea-pigs and small fowls died, after subcutaneous inoculation, with a white exudation at the needle wound. If cultures were pencilled into the open trachea of rabbits, fowls, and pigeons, there appeared a widely distributed and characteristic pseudo-membrane. These bacilli were not found in every case of diphtheria; they required a broken surface for inoculation. Young animals were more susceptible to their action than old. They were found in one out of thirty examinations in the mouth of a healthy person. These experiments have been generally accepted as trustworthy by all bacteriologists. Recently d'Espine, of Geneva, "has never failed to find Löffler's bacillus in true diphtheria and has produced the disease by inoculating with pure cultures."

To say the least, this bacillus, which only grows on the surface and is never found in the body, merits careful consideration in studying the etiology of this disease.

Let us now proceed to the study of this question from a clinical standpoint.

At the onset it will be necessary for us to inquire whether our knowledge of the action of bacteria in producing disease is consistent with the local nature of a disease with such severe constitutional symptoms. In answering this inquiry it will only be necessary for us to cite certain facts well established by experimental inoculations.

(*a*) Some bacteria in their growth in organic matter produce poisonous alkaloids or ptomaines.

(*b*) These alkaloids, which in several instances have been isolated, analyzed, and obtained in crystalline form, will, when introduced into the bodies of animals, produce a definite chain of symptoms. One of these, viz., mydaleine, isolated by Brieger from putrefying human cadavers, gives rise to the following symptoms: increased secretion from the nose, mouth, and eyes; injection of the vessels of the ear; rise of temperature and chill; involuntary passage of urine and feces; convulsive movements, in some instances; paralysis of legs; great dyspnœa, and death.

Here we have most profound constitutional symptoms produced by a chemical product of microorganisms and not by the microörganisms themselves, for none was introduced.

It is a waste of time to cite other testimony on this point since not only experimental ptomaine poisoning, but abundant clinical testimony fully establishes the fact that it is not necessary to invoke the aid of microörganisms growing and multiplying in the body of an animal, in explanation of constitutional symptoms as profound and as severe as those of diphtheria. But we must also inquire whether the pathological changes in various parts of the body are inconsistent with the local nature of this disease.

[1] Read before the Cincinnati Academy of Medicine, January 21, 1889.

The lesions on the part of the lungs, such as pneumonia, bronchitis, and atelectasis, may be accounted for by the direct extension of the membrane and by the aspiration of foreign particles and poisonous products into the smaller bronchial tubes. Fatty degenerations of the heart, liver, and kidneys are almost constant results of fever, as shown by Welch in his Cartwright Lectures, 1888. Lymphatic enlargement, congestion, and ecchymoses of the kidneys and other organs are known to result from irritating chemical agents. These pathological changes then occurring in diphtheria are not more readily explained by supposing that a special diphtheritic germ grows and multiplies in the body than they are by adopting the local nature of the disease and attributing them to the action of poisonous products absorbed from the local lesion.

This view is, therefore, not inconsistent with either the symptomatology or pathology of diphtheria.

Let us next inquire whether the microörganisms or the ptomaines are directly responsible for the constitutional symptoms of diphtheria. This is a question which at the present time requires little argument, since the evidence furnished by the clinical history of the disease points conclusively to the fact that they are produced by ptomaines. But not only clinical observations, but also experimental inquiries seem to testify that all microörganisms, whether they grow inside or outside the body, produce constitutional symptoms only through the agency of ptomaines. Welch, in his Cartwright Lectures, 1888, carefully sums up existing testimony, and concludes that fever (which is a typical constitutional symptom), is caused by the action of "pyrogenic" chemical agents which act through the nervous system. These agents are produced by the growth and activity of cells usually vegetable, viz., bacteria, but occasionally animal, viz., biological action of cells of organized tissue.

Certain points established by the ptomaine investigations of Brieger are instructive in this connection. The ptomaines isolated by him from putrefying nitrogenous materials, while not identical, were very similar in their physiological action, differing from each other more in the intensity than in the character of the symptoms produced. These symptoms were also very like the constitutional symptoms of the acute infections. This would indicate that a like cause produced the symptoms in both instances. But a fact that bears more directly on the question under consideration is that one of these alkaloids, mydaleine when introduced into the bodies of animals, produced (as may be seen by reference to its action as given above), symptoms very similar both in character and order of appearance to those of diphtheria. Even the paralysis and heart failure occurring during an attack of diphtheria find an analogue in the paralysis and dyspnœa of mydaleine poisoning; we feel justified, therefore, in attributing these symptoms to the direct action on the nervous system of the poisonous chemical products which are producing the other symptoms.

It may be interesting in this connection to inquire into the cause of the post-diphtheritic paralysis which occurs from two to six weeks after ptomaine absorption from the local lesion has ceased. It does not seem possible that soluble alkaloids, which are so readily excreted, could be followed by symptoms directly traceable to their action so long after their disappearance from the body. The theory recently advanced by Dr. William H. Thomson, that this symptom is due to a post-diphtheritic ptomaine formed by the biological activity of the cellular elements of the body consequent upon the extensive tissue-changes occurring during convalescence is, I think, not tenable, since we have no evidence whatever that a ptomaine having such a peculiar, uniform, continuous, and selective action on the nervous tissue is ever formed, let alone by a process concerning which in this regard we know so little, but, even if such a ptomaine were formed under these conditions, it would follow not only diphtheria, but also typhoid fever, septicæmia, and other prostrating diseases, which have, with rare exceptions, no after-paralysis. We have, therefore, no satisfactory explanation of the post-diphtheritic paralysis in the direct action of ptomaines, but I think we can find a plausible explanation for this symptom in the degenerative peripheral and central nerve lesions so frequently found on careful examination. These changes in the nerve tissue probably have their origin in the action of the same ptomaines which produce paralysis and heart failure during the height of the disease, and these changes thus initiated continue, because of the leucocythemic condition of the blood and general lack of tone of the whole organism, to the production of such structural lesions that paralysis finally results. In a recent paper read before the New York Academy of Medicine, Dr. J. Lewis Smith offers several objections to the theory that diphtheritic paralysis results from anatomical changes, but these objections apply for the most part, if not exclusively, to the paralysis occurring during the attack and not to the post-diphtheritic form. The mutability and early appearance of the paralysis during an attack, argue nothing against this explanation, since at this time this symptom is produced by the direct action of ptomaines.

The fact that "cases do occur in which carefully conducted microscopical examinations reveal an apparently normal state of the nerves supplying the paralyzed part, and of that part of the cerebro-spinal axis from which the nerves arise," may be explained to accord with the above hypothesis as follows.

Post-diphtheritic paralysis is not a dangerous symptom, and the opportunities for investigating its cause by post-mortem examinations are, therefore,

comparatively rare. On the other hand, the paralysis occurring during the attack is a most dangerous symptom, and furnishes ample opportunity for the post-mortem investigation of its cause. For these reasons, then, we would suspect not only that cases would occur in which there was no structural change in the nerve tissue, but that this would be the rule and not the exception. We believe, therefore, that this is the most satisfactory explanation that has been offered for diphtheritic paralysis. During the attack it is caused by the direct action on the nervous system of poisonous products absorbed from the local lesion. After the attack it is caused by degenerative changes in the nerve tissue which were initiated by the action of these same poisons.

From what has been said it is evident that our medical knowedge at the present time points strongly to the conclusion that the constitutional symptoms of diphtheria, including the after-paralysis, are produced either directly or indirectly by ptomaines.

In the logical consideration of our topic, the next question asking solution is: Are these ptomaines formed inside the body or at the seat of the local lesion?

There is scarcely a competent observer at the present day who believes that the local lesion is a mere symptom of a constitutional disease not having any influence other than a local one on its course and duration. All recent writers on this subject agree with Dr. Jacobi in accrediting the local lesion with causing in part the septic symptoms, and greatly increasing the dangers of the disease.

The question then narrows itself down to this: Are the ptomaines formed only at the seat of the local lesions, or are they also formed in the body? In other words, do the microörganisms which cause diphtheria produce their poisons only by their growth in or upon a mucous membrane or surface of some cavity or wound which communicates with the external air, and are the constitutional symptoms always due to the absorption of these poisonous bodies by the bloodvessels and lymphatics of the part affected; or do we have, in addition to this process, these germs living and producing their poison inside the body, away from the external air, and at points remote from the local lesion? Let us see what light can be thrown upon this question by the clinical history of this disease.

In tonsillar diphtheria we have little or no fever, very slight glandular enlargement, and almost no septic or nervous symptoms. In short, the constitutional symptoms are very slight, and our attention is called to the child's throat by the local engorgement and pain, and the diagnosis is made by the characteristic local lesion. The explanation for this is, that the tonsillar tissue being so poorly supplied with lymphatics, does not furnish the means for the ready absorption of the poisonous materials formed on its surface, and, therefore, the constitutional symptoms which are produced by these poisons are present only in a very slight degree. This in itself is sufficient proof that tonsillar diphtheria is a purely local disease. For, if the tonsillar disease were but the local expression of a constitutional malady, or if it were the initial lesion of a constitutional disease, then the symptoms would not be dependent, as we know them to be, on the lymphatic distribution of the part affected not only for their intensity, but for their very existence throughout the course of the disease.

The fact that a certain amount of absorption does take place in tonsillar diphtheria, as is shown by the slight constitutional symptoms and lymphatic enlargement, clearly proves that the diphtheritic germs, if they could live within the body, would find ample opportunity for entrance, at least in small numbers, into the blood and tissues of the animal.

The fact, which is amply proven by clinical testimony, that the ptomaines of diphtheria are very virulent, would strongly indicate, since these are the weapons with which the germs fight, that the lymph-cells and other elements of the body would wage a very unequal contest with these organisms should they find an entrance into the body.

The fact apparently proven by Watson Cheyne's investigations, that the dose of the virus in very susceptible animals has nothing to do with the course or termination of the disease, since some children are certainly very susceptible to diphtheria, would indicate, in connection with the two facts just recited and the clinical history of the disease, that the diphtheritic germs cannot live in the body of an animal. For, if this were not the case, the germ's facility of entering the body, its rapid multiplication, and the virulence of its ptomaines, would enable it to produce just as severe and fatal disease when the local lesion is in the tonsil as when it is in the nasal cavity. Probably the only influence which the size of the dose of the virus absorbed from these surfaces could have on the course of the disease, would be in lengthening or shortening the stage of incubation.

For these reasons, then, we conclude not only that tonsillar diphtheria is a purely local disease, but that the diphtheritic germ is strictly an external parasite.

Nasal diphtheria is a dangerous and dreaded disease, which gives us a clinical picture in which it is hard to trace any resemblance to the tonsillar disease which we have just described. Its characteristics are: high fever, great glandular enlargement of the deep cervical lymphatics, profound nervous symptoms; in fact, the constitutional symptoms so overshadow the local symptoms, that the latter, from a prognostic standpoint, are scarcely to be regarded at all, and are only of interest to us from a diagnostic standpoint, unless the local lesion is in some manner responsible for the constitutional symptoms,

then they would have an immense therapeutic and prognostic import to us, and such, in fact, is the case.

Dr. Jacobi says that on the thorough irrigation and disinfection of the nasal cavities hangs every life in nasal diphtheria, and just in proportion to the thoroughness and frequency of the washing of the local lesions, the fever, the septic symptoms, and the cervical lymphangitis are abated. The explanation for this is apparent to the merest novice in medicine, viz., the parts are so cleansed of the poisonous materials, which, on absorption, are causing the constitutional symptoms, that only the minimum amount of this material is left behind to be taken up by the thirsty lymphatics and bloodvessels of this very vascular part, probably of all surfaces, in or on the body, the best adapted for absorption.

If diphtheria is ever a constitutional malady, it is so in just this form we are describing, and yet, we have in this extract from its clinical history the most direct testimony that it is purely local.

That the profound constitutional symptoms are not produced by diphtheritic germs, growing and multiplying in the blood or tissues of the child, is amply proven by the fact that these symptoms are abated by treating the local lesion. For, if the diphtheritic germs found entrance into the body, and could grow and multiply there to the extent of producing the deep septic symptoms of that disease, as well might we hope to influence the constitutional symptoms of syphilis by washing the chancre, as to hope to influence the symptoms of diphtheria by washing the gateway by which these germs entered. Our knowledge of the physiological properties of bacteria plainly teaches us that these germs would multiply so rapidly in the body, if the conditions were favorable, and they certainly would be if such profound symptoms resulted from their action there, that the comparatively small portion absorbed from the local lesion during the course of the disease would have no appreciable effect on the symptoms, and the washing away of these germs, and the products of their growth could not in any way influence the course of the disease. For these reasons, then, diphtheria is a purely local disease.

That the deep glandular enlargement is not due to the migration of diphtheritic germs along the lymphatics is, in like manner, amply proven by the fact, that this enlargement begins to disappear with the thorough irrigation and disinfection of the nasal mucous membrane upon which the lymphatics communicating with the enlarged glands open. If the germs migrated to the lymphatic glands and there produced irritation by their development, then the glands themselves would be the site of an active diphtheritic process, and the disease would continue whether the source of the contagion were removed or not. This, as we have just seen, is not the case, and, therefore, the lymphatic enlargement cannot be thus explained.

On the other hand, if the glandular enlargement be due to irritation of chemical products taken up by the lymphatics from the seat of the disease, then this enlargement would abate when the surface of absorption was kept clean and free from the poisonous materials which was causing the irritation, and this, as we have before noted, is the case. The fact that this explanation of the glandular enlargement is supported by clinical observations is very strong testimony in proof of the strictly local origin of diphtheria; for, if the diphtheritic germs ever thrive in any part at all removed from the local lesion and within the tissue of the animal, it must be in the neighboring lymphatic glands. The occasional long-continued or permanent enlargement of the lymphatics following diphtheria can be readily explained by allowing that diphtheria, like other local diseases or injuries, may awaken in the glands a latent tuberculosis, or syphilis, which remains as an active disease after the diphtheria has disappeared. This lymphatic disease would, in turn, cause a chronic irritation or congestion of the mucous membrane of the nose and throat, which would, by reason of the fact that it furnishes a favorable soil, predispose to a second attack. This, it seems, is a much better explanation than to suppose, as Dr. Jacobi does, that the enlarged glands contain the latent diphtheritic germs which are called to the surface and into activity by some local irritation of the throat or nose, especially since this explanation, as we have shown above, seems inconsistent with clinical facts. Again, if second and third attacks of diphtheria are to be explained by the lymphatic glands holding the latent germs, then these germs would be called to the surface at a point where the lymphatic distribution communicating with the diseased glands was freest, viz., the nasal mucous membrane, and the vast majority of second and third attacks would, therefore, be primarily nasal; but this, every clinictian knows, is not the case.

If, on the other hand, the explanation be sought in some chronic irritation of the mucous membrane of the nose and throat, resulting from such causes as lymphatic tuberculosis and syphilis, which upon slight provocation would furnish a predisposing factor in a favorable soil for the growth of the germ, then the disease would first appear with greatest frequency, other things being equal; at the point in the throat most exposed to the diphtheritic poison, viz., on the tonsils and pharynx; and further than this, one attack of diphtheria would predispose to other attacks not in most persons, but only in those in whom there was a previous constitutional blight or latent disease of the lymphatics, by reason of which the mucous membrane of the throat and nose

did not return to a normal condition after the subsidence of the diphtheritic attack. The number of the second and third attacks is so small in proportion to the number of first attacks that they can readily be accounted for in this way. Further than this, it is my belief that one attack of diphtheria not only does not predispose to other attacks, except in the way mentioned, but, on the other hand, gives temporary immunity in proportion to the severity of its constitutional symptoms. The more severe the attack the longer the period of immunity. The fact that second and third attacks are usually mild and, as a rule, follow mild first attacks, lends support to this view.

Immunity is the most obscure chapter relating to the infectious diseases. We know that there is a natural immunity and an acquired immunity against *self-limited* infectious diseases. Of the latter, we know that it results from a previous attack of these diseases. It occurs to us that the causes which give to these diseases the characteristic of self-limitation and check their progress must be the same which give the after-immunity. If this be true, diseases such as malaria which do not confer immunity are not self-limited. Why is the convalescent diphtheritic patient not always reinfected by his own virus? Why does he not contract the disease from his brother and sister who are suffering from it during his convalescence? Why does not the membrane return to the tonsils after an excursion into the pharynx, larynx, or nasal cavity? These questions, I think, can best be answered by supposing that the disease has been terminated by the acquisition of a temporary immunity on the part of the patient, which continues for a longer or shorter time protecting him against future attacks. The occasional second and third attacks occurring during convalescence, even if they be due to reinfection, are but exceptions, which show the value of this pro tection.

The limits of this paper will not permit the further consideration of our topic from a clinical standpoint, reference only can be made to the fact that when diphtheria attacks the larynx, which is almost devoid of lymphatics, we have an example of a purely local disease without constitutional symptoms and when it attacks the trachea, which has not a very free lymphatic distribution and is filled with mucous glands, we have a severe local disease with mild constitutional symptoms. From clinical evidence we arrive at the conclusion that diphtheria is a local parasitic disease in which the constitutional symptoms are caused solely by the absorption of poisonous materials from the diseased surface, or, as Watson Cheyne puts it, by septic intoxication. The degree of this septic intoxication will depend on the anatomical structure of the part on which the germs grow, in reference to its hindering or promoting absorption.

The next question which we wish to consider is, What evidence have we, other than clinical, that the cause of diphtheria is not an *internal* parasite? Evidence purely negative in character may be obtained by an examination of the blood and tissues of animals sick or dead from this disease.

The failure of the most renowned bacteriologists to find the specific germ in the body is negative testimony of considerable value in the light of our present knowledge, although the specific germ may not as yet have been positively identified. The failure to find in the body the characteristic membrane which is the product of the growth of this germ and which we, from a clinical standpoint, have come to recognize as the *sine qua non* of its existence, is also valuable evidence on this question. If the diphtheritic germ were an internal parasite, we would expect to find in post-mortem records abundant evidence of this fact in the frequent occurrence of the membrane. Do we find this to be the case? Not by any means; but, on the other hand, in marked contrast are the findings at rare intervals, in ulcerative endocarditis complicating diphtheria, of a process resembling that of diphtheria. When these facts are considered in connection with the differing opinions of pathologists as to the exact characteristics of the membrane, it renders it far from certain that the diphtheritic growth has ever been found in the body. Inoculation experiments with matter from the diphtheritic membrane furnish abundant and apparently conclusive testimony on this question. It is quite evident that, if the germ is an internal parasite, the sure and rapid method of producing this disease would be by subcutaneous or submucous inoculation. But with the multitude of inoculation experiments that have been performed, we have no evidence whatever that the disease can ever be produced in this way; at times a diphtheritic process would be set up in the needle wound, but this undoubtedly came from surface inoculation. On the other hand, if the broken surface of a mucous membrane or wound of the skin were inoculated the disease almost always resulted. From these experiments alone I think we are warranted in the conclusion that the diphtheritic germ is not an internal parasite. It must, therefore, be strictly an external parasite incapable of living in the body of a living animal.

Let us next consider the question, Is the diphtheritic germ strictly aërobic? In other words, does it require free oxygen for its growth and development. A. d'Espine and C. Picot stated in 1877, that the membrane could only be developed in contact with the atmospheric air. Eustace Smith says: "The more usual seats of the false membrane are the tonsils, uvula, soft palate, back of the pharynx, nasal passages, larynx, and trachea; less commonly it is found on the conjunctiva, at the borders of the anus, in the vagina of girls, upon the glans penis,

wounds of the skin, and the external auditory meatus," and does not mention the stomach and intestines. It is evident from this, that the mucous membranes removed from the external air are comparatively exempt from the disease. Jacobi says: "The upper part of the œsophagus over a surface of one-half to one inch is often covered in cases of the extensive pharyngeal and laryngeal diphtheria. The upper portion of the deposit is very much like the adjoining pharyngeal membrane, but the lower part is thinned out into a mere film."

This is a good example of the further extension of the membrane being checked by the sparseness of atmospheric air. Food and water passing over the diseased surfaces in the throat furnish better facilities for the transmission of the germs into the œsophagus and stomach, than is furnished by the air for their transmission into the larynx and trachea. Yet, the latter is one of the most common, and the former a rare, site of this process. The presence of acid may account, in part, for this comparative immunity of the stomach, but, it cannot explain the rarity of the disease in the lower part of the œsophagus and the large and small intestines, since these latter might be affected by the upward extension of the membrane from the anus.

While the infrequency of the membrane on those portions of the mucous membrane of the digestive tract removed from the external air would indicate that the germ is almost aërobic; yet, its occasional appearance in the stomach and intestines would be evidence that it is not strictly so, since free oxygen is not one of the gases of the intestinal canal. The rarity with which the diphtheritic exudation is found in the stomach and intestines, would indicate that some pathological change in these parts is necessary to furnish the conditions requisite for the growth of the germs.

These conditions, we conclude from knowledge of its habitat, must be such as will furnish it with oxygen either in a free state, or in such unstable combination that it can be utilized by the germ in its growth. Such an unstable compound we have in the oxyhæmoglobin[1] of the blood. A congested and eroded mucous membrane would, therefore, be the pathological condition which would bring the germ in contact with this body from which it would derive its oxygen.

The fact that germs, such as anthrax, which are classed as strictly aërobic, can live and multiply in the body, deriving their oxygen from this source, is sufficient evidence that this explanation is not far fetched. We conclude, therefore, that the diphtheritic germ is practically, if not strictly, aërobic.

We must not fail to note that diphtheria may be complicated by the entrance into the body of septic germs taken up by lymphatics and bloodvessels from the diseased surface. In this manner we may have a true septicæmia developed with the germs causing the disease growing and multiplying in all parts of the body. This may furnish us with an explanation of the so-called malignant form of this disease and with the ulcerative endocarditis which occasionally occurs. A complication, such as this, might so overshadow the original disease, that the local treatment of the diphtheritic surface would have no appreciable effect on the constitutional symptoms, for the septic germs would find in the cellular elements of the body, weakened by the action of the diphtheritic poison, ready victims. We may also have less dangerous complications, such as abscesses about the lymphatics of the neck. These may be caused by the entrance of some of the germs known as the pus-formers, or by the awakening into activity of certain latent germs capable of producing the same condition. While these complications, which are not of frequent occurrence, may be constitutional, the orignal disease remains purely local.

In conclusion, we may summarize the following points from the arguments presented in the paper:

1. Diphtheria is a purely local disease.
2. It is caused by an external parasite.
3. This parasite is practically, if not strictly, aërobic.
4. The constitutional symptoms are due to the absorption of poisonous materials, viz., ptomaines, from the local lesion.
5. The changes occurring in the blood and tissues, including the late nerve lesions, are caused by direct or indirect action of ptomaines.
6. This disease has no latent stages, and second and third attacks are due to reinfection.
7. One attack, as a rule, gives at least temporary immunity.
8. After the limited period of immunity has expired, the previous attack may act as a predisposing cause to other attacks, if it has left the mucous membrane of the throat in an irritated and inflamed condition. This is more likely to occur in scrofulous subjects.
9. Complications may occur from the entrance into the body of septic germs.

If these nine propositions embrace the true points in the etiology of diphtheria, then they are of vital importance to us in the treatment of this disease.

Upon these propositions the following rules of treatment may be formulated:

1. Dissolve away the membrane, if possible, and irrigate thoroughly and frequently with an antiseptic solution the local lesion, for the double purpose of washing away the poisonous alkaloids and retarding the growth of the parasites.
2. In diphtheria of wounds, and in other parts

[1] That the germ might receive its oxygen from this source was suggested to me by Dr. W. S. Christopher.

where it is practicable, the thorough irrigation should be followed by a dressing which would exclude the atmospheric air. This on account of the aërobic nature of the germ.

3. We should try to relieve the system of the poisonous alkaloids by mild catharsis—free diuresis and diaphoresis, with remedies which do not have a depressing action on the heart.

4. We should seek to counteract the depressing effects of this poison on the heart and other tissues by abundant stimulation.

5. We should also seek to counteract its deteriorating influence on the blood by the free exhibition of the great blood restorer, iron.

6. We should render the air of the sick-room as nearly aseptic as possible, to prevent the entrance of adventitious septic germs.

7. Chronic glandular enlargement, or other local disease in or about the throat, left as the sequel of diphtheria, should be given the most careful consideration, and, if possible, thoroughly cured before dismissal. If this cannot be done, the patient should be warned against future exposure to the diphtheritic poison.

8. The patient should not be entirely dimissed from observation for two months after the attack, and during this time with tonics and judicious feeding we should assist nature in restoring the blood and tissues to their normal condition, that they may resist the degenerative nerve changes which cause the after-paralysis

9. A serious exacerbation of the symptoms in any form of ulceration or catarrh of the stomach or intestines occurring in a patient exposed to the diphtheritic poison should lead us to suspect diphtheria of these parts, and we should treat the case accordingly.

272 MADISON STREET, NEWPORT, KY.

SARCOMA OF THE TONSIL.[1]

BY ALEXANDER W. MACCOY, M.D.,

PROFESSOR OF DISEASES OF THE THROAT AND NOSE IN THE PHILADELPHIA POLYCLINIC AND COLLEGE FOR GRADUATES IN MEDICINE, ETC.

Primary sarcoma of the tonsil—so far as cases have been put on record—appears to be a rare disease, and the meagre literature on the subject, as given in the *Index Medicus*, verifies this statement. This especially applies to past observations. Current literature offers a far greater proportion of cases, the years 1886 and 1887 being particularly rich. This can probably be explained by the greater zeal manifested throughout the world in the study of laryngology; in the increased number of observers now at work; together with the exact methods of study now in vogue.

The object of this paper is not so much to give a complete bibliography of the subject (although I have appended to the history of my own case an epitome of cases recorded so far as they were accessible to me), but with the hope of bringing out in discussion the comparative frequency of sarcoma of the tonsil, as shown in the wide experiences of members of this Society.

The history of my own case is as follows:

Mary A. W., mulatto, aged forty-five, native of New Jersey, married, no children, first came under my care in May, 1886. The short family history is as follows: her father died of paralysis at seventy years of age; her mother is still living and in good health, aged about seventy; a maternal aunt died at an advanced age of a tumor of the breast, said to be cancerous; an older sister of the subject of these notes also died of a tumor of the breast of a malignant character, at the age of fifty; the other children are healthy, and are still living; a niece and nephew had died of consumption of the lungs one or two years before she came under my observation. The history of her father's family was good.

Her general health had been moderately good, but her menstruation had always been very irregular. She suffered from a menstrual flow which often lasted for several months, and after ceasing would not again appear for as long as six months. This state of affairs continued during her married life. No history of abortions or miscarriages could be made out.

On the 15th of May, 1886, the patient presented herself for treatment, complaining of a soreness on the right side of her throat, which rendered deglutition somewhat painful. She stated that this soreness had only been present for a few days, and she thought was not different from what she had often had before. Her general condition was good; flesh and strength maintained perfectly. Examination revealed on the *right* side a redness with but little swelling of the tonsil, accompanied by the slightest flushing of the anterior palatine fold in its lower half. The tonsil gave all the appearances of a tonsillitis of a mild type. Appropriate treatment was advised, and, with the injunction to let me see her again the following day if not improved, she was dismissed.

At least three weeks intervened between the first and second visits. At the second visit the previous symptoms and appearances were accentuated. The tonsil was a trifle larger, and showed a cleavage through its substance irregular in direction. A probe pressed into this fissure for about one-third inch with a little force could separate the two lips for a considerable distance. In this fissure, and hanging from it, was a grayish, pultaceous, irregular mass of tissue, which was quite movable, but adherent to the bottom of the fissure; this mass gave off a fetid odor, and led me to believe that a small abscess in the tonsil had become gangrenous and the outer wall had sloughed away, causing this appearance and retaining some of the decomposed contents. There was nothing in the appearance in color or form of the tonsil to warrant an opinion of

[1] Paper read before the American Laryngological Society, Washington, September, 1888.

other than a simple inflammatory condition. The cleavage was peculiar, it is true, and yet *could* be explained as above stated. The sloughing fissure was washed out and a solution of carbolic acid, iodine, and glycerine applied. In a few days the fissure was perfectly clean and the odor gone; the redness had abated considerably. The adjacent tissues appeared healthy. The general health of the patient had not suffered nor had she lost flesh. There was no lymphatic glandular involvement whatever present, neither was there any until very late in the progress of the case.

After several weeks absence the patient again reported for treatment, having, during the interval, enjoyed freedom from any unpleasant symptoms until a few days previous, when some uneasiness and pain in swallowing occurred. The local appearances were strikingly changed, the tonsil remained comparatively small and with little appreciable change in color (indeed the tonsil itself never increased much in size, but remained throughout the disease in about the same condition), but the anterior palatine fold had become infiltrated, thickened, shiny, and grayish-red; having a zone of deeper redness, as a limiting margin, shading off quickly into sound tissue.

This involvement embraced all the ascending portion of the anterior palatine fold; the appearance of grayish-redness resembled that of a gumma in a striking degree. Upon pressure the swelling felt somewhat like that of an erysipelatous inflammation of the face—possibly less brawny. This appearance remained for a few days with a slow involvement of the half arch and palate, when suddenly a small whitish spot appeared in about the centre of this right half arch, which rapidly increased in extent and soon showed a loss of tissue in the fold—very material and threatening complete destruction of it.

There appeared to be considerable œdema bounding the destructive process: the color was darkish red. The destruction of tissue embraced a large portion of the fold, and when it had ceased the appearance of the fold and arch was ragged, thickened, and red; the uvula was well over to the opposite side. The process of involvement never completely destroyed the uvula, but for a long time did not appear to cross the median line, and at no time was there any involvement of the opposite side, although late in the disease the left side was greatly encroached upon by new developments.

A stage of quiescence intervened with a general improvement of all the symptoms, and a faint hope of arrest. Her strength and spirits were still unimpaired.

After this stage of quiescence had continued for some weeks, upon rhinoscopic and laryngoscopic examination an irregular mass of red, velvety tissue was noticed behind the posterior palatine fold. Its long diameter was vertical, and extended from a line a little below the lower line of the tonsil, and continued well up behind the palate to the margin of the Eustachian tube. This mass grew rapidly at first and pushed out prolongations laterally which were about one-half inch in thickness and appeared to spread out *over* the posterior pharyngeal wall and to be *movable* upon it, so that a probe could be passed underneath its free edge for some little distance until it came in contact with its hardened base springing from the lateral wall. This mass continued to push out and spread over until that half of the pharynx was materially encroached upon. Again there was a destructive process set up and sloughing, followed by relief of encroachment and a stage of abeyance of all activities.

This stage continued for an interval, followed by re-development in this region as well as in that of the palate. From the free and ragged edge (which had made efforts for a time to heal) there sprung out a soft, velvety fringe, red and glistening, which was accompanied by increased infiltration of the palate followed by sloughing. This process was repeated again and again during her illness until the border of the hard palate was reached on the right side where the destructive changes ceased, and toward the end of the disease the edge of the hard palate appeared to act as a breakwater to the further progress of the disease in that direction.

After the lateral and posterior wall had been subjected to repeated involvements and the space fully occupied by the growth in the region before mentioned, the *lower* portion of the mass began to interfere with the base of the tongue and somewhat with the play of the epiglottis, rendering the swallowing of fluids somewhat hazardous. This condition was, however, for the most part confined to the latter end of the disease, and for many months respiration and deglutition were accomplished with comparative comfort.

After some eight months the upper end of the growth began to make respiration through the right nostril difficult; and toward the end it became impossible. After about six or seven months the base and sides of the tongue showed implication. The tongue appeared to become involved through the medium of the lateral ligament and from there extended over the right side of the tongue, and then downward toward the base.

The disease also crept along from the angle of the jaws to the gums; from there to the mucous membrane of the cheek, and gave rise to some swelling of the cheek, externally, and inability to close the mouth. As soon as the tongue, gum, and cheek became involved the sub-maxillary gland began to swell and attained the size of a small walnut; the lymphatic glands which, appeared to be so long in showing involvement, at about eight months began to become indurated in the side of the neck and were slightly tender; they never increased much in size.

For some weeks prior to her death deglutition became very difficult and painful; respiration was impeded so much that tracheotomy seemed at times almost imperative. As soon as deglutition began to be *very* difficult—at about nine or ten months—the patient rapidly began to fail in strength and lose flesh; the emaciation was accelerated toward the end, as difficult respiration and pain were added to lack of sustenance caused by difficult deglutition.

A day before her death an attempt was made by

her relatives, against my advice, to remove her to her former home, and although warned that she would certainly die in the attempt, they carried out their wishes, and the patient died suddenly in the carriage on removal from the train.

Much to my regret, no *post-mortem* was obtainable, being out of jurisdiction.

The treatment was non-surgical, and to many it will doubtless appear strange that some active surgical measures were not instituted.

There were several factors present which prevented a prompt decision for an operation:

1. The rarity of the case and want of a clear diagnosis.

2. The want of distinctive features while the tonsil alone was involved, having all the appearance of a tonsillar inflammation, and the absence of the patient during the critical period of the few weeks when surgical interference would have been most effective.

3. A necessarily unsatisfactory report from the microscopist to whom I gave a too small portion of the growth for examination.[1]

After the involvement of the lateral and posterior wall, several consultations were held, and the opinions being adverse to a radical operation, it was abandoned.

The medical treatment consisted of the administration of Donovan's solution, beginning with the usual dose, and gradually increasing until fourteen drops were taken, three times a day. It was remarkable how large a dose could be taken for so many months without the slightest gastric derangement or constitutional injury.

The local treatment consisted of galvano-cautery, lactic acid, and, finally, for many months the application every few days of a solution of crystallized iodine and crystallized carbolic acid 1 to 4. This appeared to control or *retard* the development better than any other remedy used, and destroyed the fetor most effectually during the stages of sloughing.

The duration of this case was one year.

In an analysis[2] of 10,100 cases of tumors occurring in four of the London hospitals, extending over periods varying from nine to seventeen years, only nine cases of *primary* tumors of the tonsil appear, and of these only *one case* of sarcoma is recorded.

Mr. Butlin, in his lectures on tumors, records only nine cases of sarcoma of the tonsil. In the *Transactions of the Pathological Society of London*, 1882, p. 331, Samuel West, M.B., narrates an interesting case of sarcoma of the *right* tonsil. The subject was a woman aged seventy-four years. There was marked glandular involvement. The duration was five and a half months.

[1] Later investigation proved it a round-celled sarcoma.

[2] Sex and Tumor Formations. By W. R. Williams, F.R.C.S. Eng. London Lancet, May, 1884, p. 934.

Mr. Lennox Browne,[1] of London, at a meeting of the Medical Society of London, March, 1887, showed a patient suffering from lympho-sarcoma of the *left* tonsil, extending down the pharynx and involving the larynx.

At the Academy of Medicine,[2] in Ireland (Surgical Section), April, 1887, Mr. Henry Gray Croly read a paper on primary sarcoma of the tonsil. He detailed the history of two very interesting cases. One was that of a lad aged seventeen years, admitted into the City of Dublin Hospital, April, 1886. The history of the beginning of this attack is remarkably like that of my own case. It began like an ordinary tonsillitis in the left tonsil (also involving the soft palate),

"and so much did the swelling resemble tonsillar abscess that an exploratory incision was made by the medical gentleman who first saw the case. No pus escaped. Glandular infiltration in the digastric space showed itself. All the usual symptoms were present—painful deglutition, dyspnœa, etc. An operation was performed. A rapid reappearance necessitated another operation. A cauterization followed this second operation. The disease returned very rapidly and the lad soon died. The duration of the disease was six months."

The second case of Mr. Croly's occurred in a man over fifty years of age. The growth was confined to the tonsil (left or right not stated), and, like the other case, so much resembled tonsillar abscess that an incision was made into the tumor. Mr. Croly declined to operate, owing to glandular infiltration. The patient subsequently died from repeated hemorrhages. Duration of disease not stated.

Prof. Weinlechner[3] reports a case of sarcoma of the left tonsil in a man fifty years of age. Infiltration of the glands at angle of the jaw and subsequent involvement of the side of the pharynx; hemorrhages requiring ligature of the common carotid. The claim is made of "arrest and disappearance of the growths" from injections of a solution of ether and iodoform 1 to 10. No microscopic examination having been made, there remains an element of doubt as to the true nature of the growth.

Zeigmondy's case[4] was of the left tonsil. Operation by the galvano-cautery. Microscopical examination showed it to be a spindle-celled sarcoma.

Dr. M. H. Richardson[5] reports a case of round-celled sarcoma of the left tonsil in a woman. Externally, induration; internally, the tonsil was pushed with the pharynx to the median line. April, 1887, the tumor was successfully removed by external incision. The upper portion of the growth extended

to the base of the skull and was difficult of removal. The patient made a rapid recovery. Seven months after the operation there had been no recurrence of the growth. Dr. W. M. Gray,[1] Microscopist to the Army Medical Museum, Washington, D. C., has some beautiful microscopic sections of a sarcoma of the tonsil occurring in a child. The sarcoma is alveolar.

This completes the list of cases of primary sarcoma of the tonsils accessible to me, and makes in all nineteen cases,[2] including my own.

1417 WALNUT STREET.

THE RESULTS IN SEVEN OPERATIONS FOR THE RESTORATION OF THE LACERATED CERVIX UTERI.[3]

BY L. D. BROSE, M.D., PH.D.,
OF EVANSVILLE, INDIANA.

IT is my intention, through the relation of these cases, to put on record the outcome of my personal experience with the Emmet operation of trachelorrhaphy, performed on what I considered proper subjects. I say proper subjects, for the reason that I do not consider it justifiable to advise or perform this operation upon every woman who chances to have her cervix uteri lacerated to more than an ordinary degree.

CASE I.—Mrs. R., æt. twenty-eight, consulted me in May, 1885, complaining of pain in the stomach, aching and tired feeling in the legs, irregular menstruation, and a gradual loss of flesh and strength. She is anæmic and suffers from irregular febrile attacks. For these symptoms a number of physicians have given her treatment for dyspepsia and malaria. She is the mother of three children, the youngest two and a half years of age, and dates her trouble from the second confinement. All of her labors have been very rapid, while the children have been of an average size. She states that the same midwife attended her in all her confinements, and that she would rupture the bag of waters immediately after coming to the bedside, labor terminating with three or four pains thereafter.

Convalescence from her puerperal periods is always slow. When she became pregnant with her third child, she picked up in flesh and apparently regained her health, only to suffer relapse after confinement.

Physical exploration.—Perineum complete. Vagina relaxed. The tissues forming the cervix uteri were greatly engorged and hypertrophied with eversion and erosion of the mucous lining of the cervical canal. There was a bilateral laceration through the circular fibres of the external os, extending higher on the left side. The position of the uterus was that of retroversion, with a sound measurement of minus three inches.

Treatment.—A Smith pessary corrected the uterine displacement, and local with constitutional treatment brought about a general improvement of health.

During the following July she became pregnant, but aborted at the end of four weeks with severe flooding. From this time on she suffered repeatedly from menorrhagia and metrorrhagia, and at times complained greatly of a bloody taste in her mouth with spitting of blood. The blunt curette was repeatedly applied, followed by applications of tincture of iodine and even fuming nitric acid. Some relief from flooding followed, but my patient became more and more anæmic and continued to suffer with irregular febrile attacks. During December of the same year she again became pregnant, with marked improvement of her general health, but abortion again followed in about four weeks. The flooding at this time was very serious and required the use of a vaginal tampon for its arrest. It returned in ten days, when after the insertion of a sponge tent into the cervical canal, a digital exploration of the uterine cavity was made, followed by the use of Sims's sharp curette and applications of Churchill's tincture of iodine. The flooding remained checked after this treatment until the next menstrual period, when she again suffered from menorrhagia.

Consent was now given for the operation of trachelorrhaphy and this was accordingly made with the use of five silver sutures. On the ninth day the wire was removed, perfect union having occurred, and my patient steadily improved and was finally restored to her usual health. Menstruation became regular and normal and the dyspeptic symptoms wholly disappeared.

On October 19, 1888, I delivered her of a strong, healthy eight pound child, after a labor of four hours duration, most of the time being taken up by dilatation of the os, and was farther gratified to have her make a rapid recovery from the puerperal period. She has discarded the pessary, and since her health continues good I have not had an opportunity of examining the cervix, to determine as to its relaceration.

CASE II.—Mrs. W., æt. twenty-five, a New England lady, consulted me in April 1886, giving a history of her first confinement eighteen months ago, since which time she has been in poor health and unable to perform her household duties. The labor was very tedious and painful owing to the child being of large size. She is troubled with whites and suffers a great deal with backache and pains in the ovarian regions, aggravated with each monthly sickness.

Physical exploration.—The uterus is in a state of subinvolution, is slightly prolapsed and retroflexed. The cervix is greatly hypertrophied, bilaterally lacerated, with eversion and erosion of its mucous lining.

Treatment.—Insertion of a Smith pessary with vaginal douches and local applications of tincture of iodine. The improvement was marked, but owing to the subinvolution and partial prolapse an operation was performed in the following May, to repair the lacerations. Seven silver sutures were employed,

[1] Since published in the American Journal of the Medical Sciences, February, 1889.

[2] Possibly twenty, if the following be a case of *primary* sarcoma, which I am unable to verify. Sarkom der beiden Tonsillen. Jahrs. ii. d. Chir. Atch. d. Spits. zu Basel (1883) 1884, pp. 29–31.

[3] Read before the Vanderburgh County Medical Society at Evansville, Ind.

after the removal of much cicatricial tissue, union becoming perfect by the ninth day, at which time all sutures were removed. Recovery of health was uninterrupted and with the support of a pessary she was soon able to perform her household duties.

September, 1888, I delivered her of a male infant weighing eight and a half pounds. The labor was very protracted, requiring some sixteen hours for complete dilatation of the os. It was necessary for her to leave her bed on the ninth day, owing to her first born having a severe attack of pneumonia, and then as a further bar to convalescence from the puerperal state, the newly born infant was attacked with severe bronchitis. The duties attending upon the sickness of these children required her to be upon her feet most of the time, occasioning by reason of this some uterine prolapse, but this was corrected by a Hodge pessary, and the patient made a good recovery from the conditions following confinement.

Case III.—Mrs. B., æt. twenty-six, a strong, healthy-looking country woman, consulted me in March, 1886, for pelvic pains, headache and backache, and an irritable bladder. She is the mother of one child some two years old, and has had a second confinement, the child, however, being born dead through the presentation being of the breech.

Physical examination.—Uterus measures minus three inches, is lower than normal, and bilaterally lacerated. The cervix is greatly hypertrophied and its mucous lining abraded. A Smith pessary was inserted and local with general treatment instituted, with benefit to the patient. May 19th, of the same year the edges of the laceration were resected freely and brought together by means of six silver sutures.

An uninterrupted recovery followed. Domestic troubles caused at this time a separation from her husband and she has since made her home with her parents.

Case IV.—Mrs. H., a German lady, æt. thirty-four years, presented herself for treatment in October, 1875. She is the mother of three girls, the youngest four years old, and since this last confinement has never regained her usual health. Her subjective symptoms are severe headaches, the pain being chiefly on the top of the head, pain in the stomach with heaviness, and dragging pains in the small of the back. Besides these symptoms she complains of leucorrhœa and acknowledges to being a very nervous person. Physical examination showed the uterus to be enlarged and heavy with a severe bilateral laceration of the cervix. The mucous membrane of the cervical canal is infiltrated and bleeds readily upon contact with the sound. The usual local treatment was instituted but without positive improvement. The headaches returned with increasing severity, associated with attacks of epistaxis, the abstraction of blood in this way affording temporary relief. She became more and more anæmic, daily congestions of the brain occurred, and lastly mental derangement followed. Irregular febrile attacks were now suffered from. The mental condition growing rapidly worse, it became necessary to be exceedingly watchful to prevent her from self-destruction. Her husband told me she frequently urged him to take his life with her, so that they might together enter the other world. These various symptoms and conditions were persistently treated with improvement of the mental condition but not total restoration. Finally consent was given to repair the laceration of the cervix uteri, and in doing this operation especial care was taken to remove as far as practicable cicatricial tissue. Seven silver sutures were placed in position and allowed to remain nine days. Good union occurred and from this onward a gradual improvement in all the symptoms followed.

Owing to Mrs. H.'s removal to Omaha some five months after the operation, I was not permitted to follow the case to its conclusion, but I have since learned through relatives that she is living happily with her family, wholly restored in mind and body.

Case V.—Mrs. M., a strong, well-developed German woman of thirty years, and the mother of two children, the youngest two years of age, consulted me for ill-health dating from her last confinement. The labor was a very protracted and painful one, and caused much mental uneasiness, owing to her living in a portion of Kansas where she was obliged to send a long distance for a physician, and labor terminating ere his arrival at the bedside. At the time of consulting me in January, 1888, she complained of congestive headaches, dysmenorrhœa, leucorrhœa, and painful digestion with irregular pelvic and back pains.

Physical examination.—Perineum complete. Position of the uterus normal. The cervix was hypertrophied, engorged, and badly lacerated on both sides, giving rise to eversion of its mucous lining. After preparatory treatment the laceration was repaired March 19th, the extent of tissue removed, necessary to secure proper coaptation, being so great as to include all the mucous membrane covering the two lips of the external os uteri. Strands of silk were inserted to reëstablish the cervical canal and the wound properly closed with seven silver sutures. On the eight and ninth days the sutures were removed, at which time union while not complete was good, and rapidly became perfect. The benefits following this operation have exceeded the expectations of the patient and likewise her doctor, headaches, dysmenorrhœa, and accompanying unpleasant symptoms wholly disappearing.

The two following cases included in this paper occured in the practice of a brother physician, whom I assisted at the time of his performing the several operations.

Case VI.—Mrs. G., a lady under twenty-six years, and the mother of one child, had a partial laceration of the perineum and a bilateral laceration of the cervix uteri. Both lacerations were repaired February 22, 1886, the edges of the cervix being brought together by catgut and the perineum closed with shotted silver sutures. Dr. —, the physician in attendance, personally drew off the urine for several days, and on the fourth day instructed the husband in the use of an English flexible catheter. Occasion arising for its use the husband attempted to pass the instrument but failed, causing his wife some pain in the effort. A short while after this, she had uternie

pain followed directly by flooding. Dr. — was hastily summoned and upon examination found the cervical laceration wholly reopened, the gut in the tissues having either given way or having been absorbed. The accident was presumably brought about by the husband passing the catheter into the vagina, against one lip of the os, and by pressure separating the partially united cervix, to which the softened gut offered no resistance. The cervix was again closed by silver wire and the patient made a good recovery, with both of the operations a success.

CASE VII.—Mrs. K., a seemingly well-developed German lady, over thirty-five years of age, and the mother of several girls, one almost grown, was operated upon by Dr. — for a multiple cervical laceration. The operation was well performed, six silver sutures being inserted. On the evening of the third day she had a chill followed by fever. Dr. — requested me to see her with him the night of the fourth day, at which time her temperature was over 105°. Antipyrin was administered with but slight reduction of bodily heat. Next morning we again saw her together, and the temperature still remaining high with frequent chills, the two lowest sutures on either side were removed, and the cavity of the uterus washed out. Death occurred the night of the fifth day due to pelvic inflammation, septic in character.

The relation of these cases besides demonstrating that this operation is capable of relieving many subjective symptoms, directs our attention to its influence on fertility and its bearing upon the character of subsequent labors. Strangely enough, the medical literature of our country as it relates to these important subjects is very incomplete. Dr. B. F. Baer, of Philadelphia, in THE MEDICAL NEWS, Feb. 24, 1883, gives as his experience, that sterility does not usually follow as a result of the operation, directly contrary to observations of Dr. P. J. Murphy, of Washington, D. C. (see *American Journal of Obstetrics* for January, 1883), who asserts that repair of laceration of the cervix uteri is usually followed by sterility.

In five of my own operations, two were followed by subsequent conception and a delivery at full term; while of the remaining three, one has lived apart from her husband and for this reason could not be expected to give anything but a sterile history, another has scarcely had one year's time to demonstrate fertility, while the third was sterile for four years preceding the operation, so that to the trachelorrhaphy cannot be assigned cause and effect.

The result of the operation in my cases bearing upon the character of subsequent labors is partially in accord with that of Dr. Murphy, who states that this is unusually protracted and severe, and that in a large percentage laceration occurs a second time.

This statement that relaceration occurs must, I think, be received with much allowance and is not at all borne out by the subsequent history of my two patients. Even if it did re-occur, I do not think that either of them would resign the benefits derived from repair of her laceration and accept her former life of ill-health.

MEDICAL PROGRESS.

Treatment of Epilepsy.—The following are the details of PROFESSOR KOWALEWSKY'S (of Kharkhow) treatment of epilepsy, as given by him in a recently published article (*Russ. Arkiv. Psych. and Neurolog.* XII., 3, 1888). He takes cases which he considers possibly curable (those in which the epilepsy dates back less than ten years) and in these he reckons the minimum period for treatment at two years. This he divides into four equal portions or semesters for convenience in detailing his method. During the first half year he gives his patient a drachm of bromide of soda or such other bromide salt as is selected, each twenty-four hours, adding usually three to five grains of iodide of soda and giving the combination in two or three equal doses in the morning, before dinner, and at night in a large quantity of water. In case there follows any decided adynamia from this quantity of the bromides he decreases the dose somewhat, or in some cases intermits it for four or five days. During this semester also he stops the treatment during the catamenia in female cases.

In order, however, to have this plan succeed, it is necessary to allow a good supporting diet, though preferably one of milk and vegetable food. If there exists any scrofulous taint, cod-liver oil or iodide of iron is also administered. In case there should be any symptoms of brominism such as headache, neuralgia, etc., in the beginning of this treatment, it is not necessary to stop the treatment, as soon as it is relaxed a little these symptoms disappear. Much advantage is had in these cases from warm baths and rubbings.

Usually this treatment causes cessation of the attacks so that the patient is free from them during the last three months of the half year. Toward the close of the semester the medication is stopped for a period from two to six weeks before beginning it again.

In the course of the second half year the quantity of bromide and iodide is reduced one-half and given in the same way, and at its end there is again an interval of two to six weeks. In the third semester only the bromide is given and in doses of five to ten grains, morning and night, keeping up the same regimen and diet. In the fourth half year he begins with only five grains per diem and later only gives the medicine at intervals of one, two, three, four, or six days. After this the bromides are discontinued and the patient is given small doses of nitroglycerine or at intervals, in some cases, tr. simulo (*capfaris coriaciac*), which is said to have a marked influence over epileptic attacks. Prof. Kowalewsky claims that he has by following out this plan of medication already had quite a number of cures, in which the attacks have not reappeared for over ten years, and that he has lost faith in the incurability of epilepsy.

Of course, in cases in which there is any specific or tubercular cause or complication the treatment must be adapted to meet the special conditions.

As regards other than medicinal treatment the author recommends electricity as an adjuvant in certain cases,

but cautions against its employment in any case in which there is a tendency to cerebral hyperæmia. He also found benefit in weak irritable anæmic cases from daily warm baths, of temperature of 25°-28° R. (88°-95° F.) for fifteen or twenty-five minutes, watching the condition and nutrition of the patient, and when these are improved using baths gradually lowered in temperature and not so prolonged. In some cases combined baths and electrical treatment are of advantage.

The author's ideas as regards diet are liberal, but he says that for all cases of epilepsy taken together, a vegetable and milk diet is best. Alcohol he forbids even in medicine, at least in the beginning of the treatment—he says he has seen the epileptic attacks revived by even a few drops of alcohol. Tea he allows in moderation, but he advises that coffee, chocolate, etc., be dispensed with at least during the treatment.

There are other points of interest in the article, but the above are the most noteworthy, especially the success that seems to have attended the author's method of using the bromides. The quantity given is certainly not large; not even in comparison with his own treatment in other cases, for he recommends as much as three or four drachms *per diem* in cases of epileptic furor. There would seem to be some special advantage in the method or the regimen presented to bring about such specially favorable results.—*American Journal of Insanity*, January, 1889.

The Treatment of Pernicious Anæmia, with Recovery.—In some remarks upon this subject (*Lancet*, Jan. 12, 1889), DR. BROADBENT said that until the publication of Dr. Byrom Bramwell's paper on the success obtained by the use of arsenic in pernicious anæmia, it was looked upon as truly progressive, and always to a fatal termination. Since that time there has been a change, and many cases have been published proving the efficacy of arsenic, recovery having frequently followed its employment; sometimes there appears to have been a relapse, and sometimes it has failed, but no treatment has yielded such good results. Iron, which in cases of ordinary anæmia is so efficacious, appears to be almost useless; but a case is recorded in which arsenic failed to cure, and the patient recovered on the administration of iron. Other treatment adapted to improve the general health, allay digestive disturbance, produce appetite, etc., has been recommended; and transfusion has been tried in some instances with success (see Coupland), but the use of arsenic is generally indicated. We dwell on this point, as a recent edition of a work on therapeutics does not draw attention to its great properties in such cases. Dr. Broadbent, in a former case which recovered, that of a woman, aged forty-three, who had been suffering for four months, gave the drug in frequent small doses, on the failure of iron, and obtained a cure in two months; in this case he followed a similar plan, giving liquor arsenicalis in two and a half minim doses every three hours.

Treatment of Baldness.—DR. LASSAR (*Therap. Ztsch.*, December, 1888) recommends for alopecia areata the following treatment: For the first six or eight weeks an experienced hand should thoroughly soap the scalp for ten minutes daily, using for this a strong tar soap. A good lather having been formed, it should be removed with an irrigator, using first lukewarm and then cold water. The cold douching will, after several repetitions, harden the scalp somewhat and prevent catching cold. After the scalp has been thoroughly dried the following lotion should be applied:

℞.—Solution of bichloride of mercury	8 grs. to 5 oz.
Glycerin Cologne water	āā ℥ij ℥v.

Then the scalp should be rubbed dry with alcohol, ninety per cent., to which one-half per cent. of naphthol has been added. The scalp now being freed from any fat whatsoever, the following is applied:

℞.—Salicylic acid	30 grains.
Tincture of benzoin	45 "
Neat's foot oil	℥iij ℥ij.—M.

This treatment carried out daily for some weeks will be followed with good results. Dandruff and itching will disappear. Hairs which are stiff and dry, become flexible and oily, and where no hair was, hundreds of small hairs will make their appearance. Of course, this only holds good when the hair-growth is not destroyed.

In very obstinate cases the following is worthy of trial:

℞.—Carbolic acid	15 grains.
Sublimed sulphur	75 "
Fat from a horse's neck	℥iss.—M.

The author relies very much upon pilocarpin, which he prescribes either in the form of an alcoholic solution or pomade:

℞.—Muriate of pilocarpin	30 grains.
Vaseline	℥v.
Lanolin	℥iiss.
Oil of lavender	25 drops.—M.

That the addition of balsam of peru to hair pomades takes the place of an antiparasite is well known and the following would make an efficient though somewhat expensive pomade:

℞.—Muriate of pilocarpin	30 grains.
Muriate of quinine	60 "
Precipitated sulphur	℥iiss.
Balsam of Peru	℥v.
Ox marrow	℥iij.

Before applying the pomade the scalp should be thoroughly washed with soap and water and allowed to dry; then the ointment should be applied, but it should not be left on too long, before being again removed with soap and reapplied.

Tar in the form of tar-baths is also an excellent remedy as well as an antiparasite.—*Münchener med. Wochenschrift*, December 25, 1888.

Curability of Cirrhosis of the Liver.—DR. MILLARD, at a late meeting of the Société Médicale des Hopitaux, of Paris, presented three patients from his private practice, in whom, after a lengthy treatment for this affection, he had been able to effect a cure.

The first was a man, fifty-five years of age, who drank regularly from four to five bottles of wine daily. Suffering from dyspepsia for several years, he, in July, 1886, began to emaciate; the supervening ascites necessitated six tappings, from which over two hundred pints of fluid were removed. Since the month of November, 1886, the

patient has been put upon an exclusive milk diet, with the administration of an infusion of juniper, and drastic purgatives twice a week. At the end of four months the improvement was already well-marked. The second patient, who partook of four pints of white wine daily, had been under the author's care for one year only. The treatment was the same as in the first case; improvement showing itself more rapidly; the patient continues in excellent health. The third patient underwent the same treatment, with greater and more marked improvement than in either of the foregoing cases.

At present the three patients seem apparently quite cured, the only remaining sign of their trouble being a slight hypertrophy of the liver.

The formula of the juniper infusion is as follows:

℞.—Juniper berries	. . . .	℥ijss.
Infused in water	. . . .	℥vjss.
Then add		
Acetate of potassium Nitrate of potassium	.	āā grs. xxx.
Oxymel of squill	. . .	℥ijss–℥j.
Syrup of five roots[1]	. . .	℥j.

The author further remarked, that he never hesitated to have recourse to tapping, whenever diuresis seemed insufficient. The only food allowed was milk; alcohol in all forms was strictly withheld. The infusion of juniper is not disagreeable to the taste. The author administered it whenever an increased urinary secretion was called for. The patients took it readily, one of them having taken it daily for eight months.—*Revue de Thérapeutique*, January 1, 1889.

Laparotomy for Ectopic Pregnancy of a Non-tubal Variety.—Professor Serghei S. Zaiaitzky, of Moscow, describes in the *Meditzinskoïe Obozrenïe*, No. 16, 1888, a successful case of abdominal section for extra-uterine gestation in a multipara, aged twenty-five. The last catamenia had occurred about the end of October, 1887. Soon afterward she began to suffer frequently from giddiness (from which she had also suffered during her previous pregnancies), while she noticed a gradual, painless enlargement of her abdomen, as well as of the breasts, with occasional oozing of milk. Four months later she began to feel fœtal movements, which, however, ceased about April 27th; the abdomen then somewhat decreased in size, and became exceedingly tender and painful. On examination, on May 30th, ectopic pregnancy—either ovarian or, more probably, abdominal—of six months' duration, with dead fœtus, suppuration of the sac, and peritonitis, was diagnosticated, and immediate laparotomy at once suggested. The woman, however, hesitated for a few days, until the pains became intolerable and vomiting came on with fever and rigors and rapidly increasing prostration.

On June 8th Dr. Zaiaitzky made a median incision down to the peritoneum, which was found to be thickened and adherent to a thin-walled fœtal sac. The latter having been cut into, very offensive, cinnamon-brown, purulent matter escaped, and an almost black, macerated, and softened female fœtus was extracted. The sac proved to consist of fibrinous membranes adherent to the omentum, bowels, and the right Fallopian tube near its abdominal opening. The fimbriæ were considerably thickened, congested and covered with false membranes resulting from recent perisalpingitis, but the oviduct presented no sign whatever of having been ruptured or dilated. The tube was ligatured about its middle, and its external portion removed with the adherent placenta and sac, after which the peritoneal cavity was washed out with corrosive sublimate lotion and three drainage tubes were inserted (one through the vaginal fornix). The operation lasted about an hour. The temperature fell to normal the same evening. On the seventh day the drainage tubes were removed. On the 22d the woman was discharged quite well.

This case proves beyond any reasonable doubt that extra-uterine gestation may sometimes be of non-tubal origin. The only change found about the oviduct was an inflammatory hypertrophy of the abdominal end of the tube. No clinical symptoms of a tubal rupture had ever been present.

In the *Meditzinskoïe Obozrenïe*, No. 1, 1888, Dr. Zaiaitzky described another successful case of laparotomy for tubo-ligamentary gestation (variety 2 *c*, according to Mr. Lawson Tait's scheme) of six months standing in a multipara, aged twenty-three. The whole sac was removed. No drainage was used. On the twenty-fourth day the patient was shown well and strong at the Moscow Obstetrical and Gynecological Society.—*British Medical Journal*, January 5, 1889.

Simple Treatment of Acute Coryza.—The *Schweizer Wochenschrift für Pharmacie*, No. 49, gives the following simple treatment for this affection:

Put one teaspoonful of powdered camphor in a cone-shaped vessel, filled with boiling water, and covered with a cornucopia, the top of which is then torn off just enough to admit the nose, and the warm camphor-vapor inhaled from ten to fifteen minutes. A repetition of this procedure after four or five hours, will generally suffice to effect a cure.—*Correspondence Blatt. f. Schweizer Aerzte*, January, 1889.

Papayotin in Fissures of the Tongue.—Dr. Schwimmer has used papayotin (which is also known as papain) successfully in cases which had resisted the action of chromic acid, iodoform, and nitrate of silver. He employed the following formula:

℞.— Papayotin	. . . .	1 to 2 parts.
Glycerin Water	. . .	āā 10 parts.—M.

Five or six applications should be made daily, after drying the fissures.—*Amer. Journal of Pharmacy*, Jan. 1889.

Phenic Acid in the Treatment of Diphtheria.—Dr. Gaucger, from ninety-nine observations made with this remedy in the treatment of diphtheria, deduces the following conclusions:

1. The treatment of diphtheritic sore throat by ablation of the false membrane and cauterizations with phenic acid is applicable to children as well as adults.

[1] Syrup of five roots (sirop des cinq racines) is a French diuretic preparation, composed of the following roots: Ash, fennel, parsley, asparagus, and small holly, each 1 part, and sugar 30 parts.

2. All adults, and *almost* all children, treated by this method have recovered. (The restriction refers to very small children, with whom treatment was begun very late, or with whom croup set in rapidly.)

3. Applied in time, this treatment can prevent croup, as has been often observed by Dr. Dubousquet.

4. Even after tracheotomy the continuation of the treatment of the throat symptoms by this same method is essential.

The formula of the application employed for washing and cauterizing the throat is as follows:

Crystallized phenic acid	75 to 150 grains.
Camphor	ʒv–ʒj.
Tartaric acid	11 grains.
Alcohol (36°) } Olive oil }	āā ʒiiss.

Besides applying the above morning and evening the throat should be irrigated every two hours with a one per cent. phenic acid solution.—*Revue Thérapeutique*, January 1, 1889.

Alopecia Areata a Communicable Disease.—DR. O. LASSAR has demonstrated through a number of cases that the great increase of alopecia areata is due to the facility with which this disease is communicated to both young and old. Pillows and headgear, the barber's combs and brushes, have all in their turn been the medium of infection. It is to avoid such infection that the Berlin authorities, at the instigation of Dr. Koch, have concluded not to supply combs and brushes for general use at the public baths.

Dandruff alopecia is very infectious, and of the accuracy of this statement, the following small epidemics are cited as proof. Ten customers of a certain barber after having had their hair cut, began to lose their hair, and finally became completely bald. The further spread of this epidemic was prevented by the disinfection of the barber's instruments and utensils.

Twenty Parisian firemen suffered from alopecia areata the cause of which was traceable to their having used the same pillow, while stationed in a certain part of the town.—*Correspondenz Blatt für Schweizer Aerzte*, January, 1889.

A Mercurial Soap.—DR. SVETULKHIN (*Russk. medits*), in order to facilitate the absorption of pleuritic effusions, employs a soap, to which he has given the name of sapo kalinus hydrargyrosus, made by mixing together metallic mercury, mercurial ointment, caustic potash, and olive oil; one-third of the weight of the soap being mercury. The author claims that it is more easily applied than the mercurial ointment and less irritating to the skin.

To apply it take from a half to one drachm and agitate thoroughly in hot water, till it forms a soapy mass. In the treatment of serous pleuritic effusion, one or two applications are generally followed by rapid improvement, and the disappearance of all unfavorable symptoms is observed after the twentieth application.—*Nouveaux remèdes*, December 24, 1888.

Prophylaxis in Cerebro-spinal Meningitis.—The Berlin police intend to issue the following regulations to prevent the spread of cerebro-spinal meningitis: 1. Every physician shall at once report to the police any case that comes to his knowledge. 2. Patients are to be isolated. 3. The children of families in which there are cases are to be kept from school. 4. The sick rooms, expectorated matter, linen, handkerchiefs, clothes, and other belongings of the patient used during the illness are to be cleaned and disinfected.—*Lancet*, January 5, 1889.

Hydrochlorate of Apomorphine.—This drug has been extensively tried by DR. SOCQUART, of Bruxelles, as a remedy for certain kinds of coughs, particularly in distressing and frequent hacking, unattended with expectoration, or with exceedingly difficult expectoration. It is, as a rule, well borne, although a few individuals manifest a special susceptibility to its action, and rarely nausea, colic, or diarrhœa result from its administration. The dose is about $\frac{1}{20}$ of a grain, taken in water once in twenty-four hours. As the solution rapidly alters by keeping, it is advised to prevent its decomposition by the addition of a few drops of hydrochloric acid, which does not interfere with its therapeutic effects.—*Amer. Journ. of Pharm.*, Jan. 1889.

Pancreatin in the Treatment of Atrophic Catarrh of the Stomach.—In atrophy of the gastric glands or in the so-called atrophic catarrh of the stomach, the results obtained from therapeutic measures have thus far not been positive; it being impossible to restore the already degenerated glands. Being convinced that neither hydrochloric acid nor pepsin or any other remedies were of any use in the treatment of this affection, DR. REICHMANN, of Warsaw, tried in ten cases (out of one hundred and seven cases treated for various gastric affections) an alcoholic extract of the pancreas (twelve to fifteen per cent.) and pancreatin, and was soon convinced that the formerly sluggish chyme digestion was now properly performed, the general condition of the patients being greatly improved.—*Deutsche med. Wochenschrift*, Dec. 27, 1888.

For Gastralgia and Vomiting.—

℞.—Muriate of morphia	4 grains.
Muriate of cocaine	5 to 8 grains.
Tincture of belladonna	ʒjss–ʒijss.
Bitter almond water	ʒvjss.—M.

Sig.—Ten to fifteen drops every hour.—*Centrbl. f. d. ges. Therapie*, January, 1889.

The Juniper Berry as a Diuretic.—According to the *British Medical Journal*, Jan. 12, 1889, DR. GOLDSCHMID, of Fehraltdorf, highly praises the inspissated recent juice of common juniper berries as the best diuretic in children. Attention was drawn to this remedy by Dr. J. Vogel, of Dorpat, in his classical handbook on children's diseases. While being most effective, the remedy is exceedingly mild and altogether free from any unpleasant accessory effect. Two or three teaspoonfuls should be given daily, diluted with water and sweetened with sugar. The little patients take it very readily. The author describes a severe case of nephritic dropsy in a girl, aged seven, in which the juice rapidly induced a profuse diuresis, a complete and permanent recovery ensuing in a fortnight.

Five Cases of Extra-uterine Pregnancy.—DR. FASOAL (*Ann. di. Ost. et Gin.*, 1888, Nos. 4 and 5) reports that of 1565 cases of pregnancy treated between the years

1883 and 1885 at the clinic of Dr. Chiara, only five were of extra-uterine pregnancy. In one of these cases in which it was impossible to diagnosticated either tubal or ovarian pregnancy, the liquid contents of the ovum were removed through vaginal aspiration, and this was followed by a series of applications of the electrical current; these applications generally terminated with severe pain, which stopped abruptly twenty days after beginning the treatment. A slight hemorrhage then followed, accompanied by a discharge of uterine secretions and a diminution in the size of the tumor which became hard and encysted.

In the second case, which was followed by the death of the fœtus through rupture of the ovum into the peritoneal cavity, laparotomy was performed, after the death of the mother, and revealed a seven month abdominal pregnancy.

The three remaining cases terminated in rupture of the cyst and recovered without surgical interference.—*L'Union Médicale*, December 27, 1888.

Thymol in the Treatment of Tuberculosis. — DR. W. PHILIPOWICZ has administered thymol to 38 patients, 17 of whom were treated exclusively with this remedy, whereas the remaining 21 were given the preparation after diarrhœa had set in. The results of the first group were: 10 improvements and 4 deaths, while 3 remained under treatment. The results of the second group are not given, as the treatment was not a uniform one. Thymol was administered in daily doses of 45 grains, being given in gelatine capsules, in which medium the burning taste of the drug was less noticeable. Under the administration of thymol a diarrhœa will generally disappear in from two to four days, except when there exists amyloid degeneration of the intestinal walls. The drug can be taken for some time without producing any harmful effects; in fact, it seemed to the author that under its administration both the appetite and digestion were improved. In hæmoptysis it diminished the cough and the expectoration, it lowered the temperature, produced a gain in the body weight; in short, a general improvement of the bodily condition, except in cases in which the disease was too far advanced.—*Wiener med. Presse*, Jan. 6, 1889.

Trigeminal Neuralgia.—

℞.—Butyl-chloral hydrate . . 30 to 75 grains.
Alcohol . . . . . ʒiiss.
Glycerin . . . . . ʒv.
Water . . . . . ʒiv.—M.

From three to four tablespoonfuls at a dose when required.—*Centrbl. f. d. ges. Therapie*, January, 1889.

Hereditary Syphilis.—At a recent meeting of the Imperial Royal Society of Physicians of Vienna, PROFESSOR NEUMANN read a paper on hereditary syphilis and presented the following conclusions: 1. A syphilitic mother may convey the disease to her offspring at any stage of her affection, whether the infection had taken place before or after the conception. 2. A mother who had contracted the disease after conception sometimes transmitted it to the fœtus. In the case of a pure post-conceptional syphilis the transmission of the affection to the child was extremely rare, and particularly when the mother had become infected in the last months of pregnancy. 3. When the infection of the mother had taken place after conception, and the father was syphilitic at the time of procreation, the effect on the offspring was greatly intensified; the children in these cases died *in utero*, or were born with signs of syphilis. 4. In the case of post-conceptional syphilis, where the infector was unknown, the proportion was the same as in pure post-conceptional syphilis; syphilis acquired in the last months of pregnancy was usually transmitted to the offspring. 5. When infection and conception occurred at the same time, the children died in one-half of the cases. It was nevertheless remarkable that a great part of the offspring remained free from syphilis, in spite of the fact that the disease was in an active state in both the parents at the time of conception. This disproved the assertion that a healthy child could never be born when both parents were syphilitic at the time of conception. On the other hand, the assertion that healthy children were born only when the syphilis of the parents was seven years old, was also negatived. 6. In the case of infection before conception, the period at which conception occurred had to be taken into account; the longer the interval between infection and conception, the more favorable was the prognosis of the offspring. 7. The offspring had the best chance when the mother only contracted syphilis in the last months of pregnancy, while the father was healthy at the time of procreation; the same was also true of the offspring of parents suffering from tertiary syphilis. The offspring had the least chance when infection and conception had occurred simultaneously, or when the father was suffering from recent syphilis at the time of procreation. 8. This last observation also elucidated the question as to paternal syphilis. It was especially these cases in which the father was syphilitic at the time of procreation, and the mother became infected only after conception, and the child was soon after the infection born in a macerated condition, which proved the extremely injurious nature of paternal syphilis. This was opposed to the observations of Boeck and Deware, who stated that the child of a syphilitic father was always healthy. These data, concluded Professor Neumann, showed the sad fate of the children of syphilitic parents, as, out of one hundred and nine cases, only forty-four were born healthy, and according to inquiries made by Dr. Friedinger, director of the Vienna Foundling Hospital, only the minority of them lived. Hereditary syphilis must, therefore, be considered one of the most terrible plagues of infant life.—*British Med. Journal*, Jan. 12, 1889.

Treatment of Infantile Typhoid Fever.—LEGROUX and PARAT recommend the following formula in cases in which the diarrhœa is marked.

℞.—Salicylate of bismuth }
Naphthol } . . āā 40 grs—M.

Divide into six powders; give one nearly every hour in unleavened bread, or milk, in either of which it is well retained, without nauseating the little patient.

If the diarrhœa is not troublesome, the bismuth can be dispensed with. If constipation is a prominent feature, administer:

℞.—Naphthol . . . . 40 grains.
Salicylate of magnesia . . 40 to 90 grains.

Divide into six powders, one every hour.—*Gazette Médical de Montreal*, December, 1888.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, FEBRUARY 2, 1889.

RUPTURE OF THE HEART.

MEYER reports from the Pathological Institute of Munich (*Deutsches Archiv für klinische Medicin*, Bd. 43, Hefte 4 and 5) 9 cases of this rare condition, and analyzes 25 cases which have been recorded in the literature since 1870. As indicating the rarity of heart rupture, he states that of the 12,000 to 13,000 sections made at the Munich Institute, since 1854, there have been only 7 cases.

The older writers believed that a normal heart might break or rupture, owing to an excess of intraventricular pressure, the result of a sudden vascular disturbance due to psychical causes; but a review of more modern literature would seem to establish definitely the fact that some prior change invariably exists in the muscle. In several cases there has been a new growth in the cardiac wall; in one instance, an echinococcus cyst determined the rupture; and, occasionally, ulcerative endocarditis, when mural, will perforate and cause death by hemorrhage into the pericardium. Practically, the great majority of cases depend upon two conditions — myocarditis and fatty degeneration. What we term myocarditis is usually the result of a lesion of a branch of the coronary artery; either an acute endarteritis, such as may occur in the specific fevers, or a chronic sclerosis of the vessel which leads to a fibroid condition of the muscle. The local disturbances of nutrition caused by the blocking of a terminal branch of a coronary artery produce the condition known as infarct of the heart; or, as it is sometimes called, anæmic necrosis. To this softening, which may be extreme, the term myomalacia has been applied by Zeigler. The danger is not alone at the period of preliminary softening, but time gradually effects a transformation of the softened areas into fibrous tissue, which yield and lead in many cases to aneurism of the cardiac wall and rupture.

In fatty degeneration we know that the most extreme grade may be reached without danger to the integrity of the heart muscle, so long as the process is uniform, but a localized fatty change which follows the gradual obliteration by endarteritis of a branch supplying a limited area of the cardiac wall, seems to precede rupture in a number of cases.

The relation of arterio-sclerosis to the changes which are associated with heart rupture, is indicated by the fact that in the majority of cases the patients are advanced in life. The mean age in Elléaume's cases was sixty-five years.

The left ventricle is the one most frequently involved. In Meyer's cases, in 25 the rupture was of the left ventricle, 7 of the right ventricle, and 4 of the right auricle. The apex of the left ventricle is usually the site of the laceration, probably, because it is in the long branch of the left coronary artery which supplies this region that the most frequent atheromatous degeneration is found. Moreover, here, at the point of the left ventricle the muscular layers are thin. The tear is usually small, but in one instance it extended from the base to the apex of the ventricle. More commonly, the opening is of a fistulous character, and oblique in direction. There may be as many as five separate breaks. The rupture is not necessarily followed by immediate death; there are cases in which the symptoms have persisted for hours or even days, probably, owing to the fact that a small laceration has occurred and which has gradually extended.

In a number of cases death occurs suddenly, without any premonition; in other cases, precordial distress, pain in the left side, and signs of cardiac trouble have preceded the fatal illness for days or even weeks.

The determining cause is not infrequently severe muscular exertion. Emotion, as excessive grief or excessive joy, though popularly believed to be frequently the cause of a broken heart, is in reality rarely mentioned as a determining factor. Undoubtedly, the direct cause of death is compression of the heart by the effused blood within the pericardium. Spontaneous healing is scarcely possible

when the perforation is direct or complete. But there is a case on record in which the pericardium adhered around the orifice with the production of an aneurismal sac, which finally led to death by perforation into the pleura.

PHENACETIN.

THE question as to the value of phenacetin as an antipyretic and analgesic is at last being determined with some degree of certainty. The studies of Hinsberg and Kast, of Rumpf, and of many other accurate observers, both in this country and abroad, have, heretofore, frequently been pregnant with contradictions and failure, and while the drug has been lauded by continental writers it has failed in England and America.

In the *Deutsche medicinische Wochenschrift* of December 13 and 20, 1888, MAHNERT, of Graz, has, in a communication entitled: "Phenacetin from a Physiological and Clinical Standpoint," given us the results of his experience with this compound. In the instances where he employed it to reduce temperature, the fall produced by it was very marked. Thus, in one case of rheumatic polyarthritis fourteen grains of phenacetin caused the temperature to fall from 102.2° to 97.8° in five hours, followed by a rise of 2.7°. The pulse-tracings before and after the use of the drug, when compared gave no evidence of cardiac depression. In another instance a temperature of 102.9° was reduced in three hours to 98.6° by twenty-three grains, but rose again in five hours to 104°, and finally reached, three hours later, almost 104.3°. At this point the drug was used again in the same dose, and there ensued a steady fall of temperature to 96.8° in five hours, remaining at this point for one hour, when it began to rise again, and in two hours reached 104° once more.

The conclusions to be drawn from these studies on the action of phenacetin in fever seem to be that it is no better than any other pure antipyretic, such as antipyrin, and that it lowers temperature much more slowly than do most of the other members of the group. Therefore, it can be employed for the reduction of temperature, not where a hyperpyrexia threatens life and a rapid fall is required, but where a more slow and persistent influence is desired.

As to its analgesic effects, our information is more meagre but more concordant. So far as we are aware, phenacetin certainly gives relief in locomotor ataxia, and in some forms of neuralgia, and the experiences of Mahnert are in accord with this belief. It may be used in headache in the dose of five to ten or even fifteen grains, provided the pain is neuralgic in character; it also has been highly praised in ovarian neuralgia and hemicrania, and in various other evidences of morbid nervous states.

THE State Board of Health of New York in the early part of the week notified the health boards in all parts of the State that the smallpox had become threatening in the Onondaga County Poorhouse, the penitentiary at Syracuse, and at Lyons and other places in Central New York. They urge all the people to get vaccinated, and directed a special lookout to be kept for tramps.

THE Boston Medical Library Association, last Tuesday evening, gave a reception to Dr. Oliver Wendell Holmes, its President from 1875 to 1888, when his medical library was formally presented to the Association and accepted.

THE Middleton-Goldsmith Lecture for 1889 will be delivered before the New York Pathological Society, on February 16th, at 8.30 P.M., at the hall of the Academy of Medicine, by Dr. R. H. Fitz, of Boston. The subject will be "Acute Pancreatitis, with an especial Consideration of Pancreatic Hemorrhage, Hemorrhagic Pancreatitis, and Subperitoneal Fat Necrosis."

A MUNICIPAL hospital for contagious diseases is about to be built for the city of Brooklyn. A plot of ground has been purchased at a cost of sixteen thousand dollars, and the further sum of sixty-five thousand dollars has been appropriated for buildings, which will be erected under the direction of the Commissioner of Health. The plans have been prepared upon the pavilion system and will admit of as many structures, rapidly and cheaply built, as any possible emergency may demand. The accommodations will be such that patients who can pay for private rooms may be received as well as others whose treatment is a public charge.

THE Empress Augusta has offered, in connection with the German Society of the Red Cross, a prize of $2500 for the best portable military hospital. The award will be made at an exhibition to be held in Berlin, in June. All countries are invited to exhibit.

In the matter of the publication in the *British Medical Journal*, in breach of professional confidence, of the "script" of the late Emperor Frederick reflecting upon one of his medical attendants, the Council of the British Medical Association, at a meeting held on January 16th, directed a letter to be addressed to Sir Joseph Lister, as the representative of the signatories to the memorials forwarded to the Council in December, stating that the Council "having received and published an expression of regret from the Editor, and having themselves expressed their strong disapproval at the publication of anything in the least degree tending to a violation of professional confidence, they feel that they have done everything which was necessary to vindicate the honor of the Association and of the profession." The Council also forwarded to Professor von Bergmann a copy of the resolution of disapproval passed last November.

The Eighth Congress for Internal Medicine will be held at Wiesbaden, Germany, on April 15 to 18, 1889. Professor von Liebermeister, of Tübingen, has been chosen President. Professor Schultze, of Bonn, will deliver an address in commemoration of Dr. Rühle. Among the principal subjects to be brought up for discussion are: Ileus and its treatment; and the nature and treatment of gout. Besides these a number of papers have been already sent in, including ones by Professor Immermann, of Basel, Professor Fürbringer, of Berlin, Dr. L. Lewin, of Berlin, and others.

A Naval Examining Board is now in session at the U. S. Naval Hospital, Philadelphia, for the examination of candidates for admission into the Medical Corps of the Navy as Assistant Surgeons. The Board will remain in Philadelphia until the 31st of March, 1889, and after that date it will hold its sessions at the Naval Hospital, Brooklyn, N. Y. There are fourteen vacancies in the grade of Assistant Surgeons.

REVIEWS.

Transactions of the Association of American Physicians. Third Session, held at Washington, D. C., September 18, 19, and 20, 1888. Volume III. 8vo. pp. xx., 404. Philadelphia, 1888.

This is the largest and most valuable volume which has yet been issued by this vigorous Association, and it represents the work done at the meeting held in conjunction with the late Congress of American Physicians and Surgeons. It contains twenty-five papers of a uniformly high standard of excellence and of marked practical value.

Where there is so much to praise it seems invidious to single out any one paper for notice, but since no adequate abstract of it was at the time published, we cannot refrain from calling attention to Dr. Jacobi's valuable contribution to the anatomy and pathology of the thymus gland, which is richly illustrated by fourteen plates. The groups of papers on typhoid fever, on the relative value of albumin and casts in the urine, on diseases of the heart, on the treatment of phthisis, on the relation between trophic lesions and diseases of the nervous system, and on antiseptic medication reflect the latest and best thought of the day, and are deserving of careful study. Dr. Sternberg's paper on his recent researches on the etiology of yellow fever, although negative in its conclusions, is also timely and valuable.

SOCIETY PROCEEDINGS.

CINCINNATI ACADEMY OF MEDICINE.

Stated Meeting, January 21, 1889.

The Vice-President, Willam Judkins, M.D., in the Chair.

Dr. B. K. Rachford read a paper on

THE ETIOLOGY OF DIPHTHERIA.

(See page 113.)

Dr. Robert W. Stewart did not think there could be any doubt among those who treated diphtheria as to its local character. It at least begins as a local disease; and the constitutional symptoms come on later. There were, however, one or two things which the speaker would not like to accept as dogmatically as the essayist presented them. First of these was that, by treating the local manifestations, we may hope to abate the constitutional symptoms. There is certainly something about this disease, in its inception, in its course, and in its results, that indicates more than merely a local character. It is, perhaps, a local disease for only a short time. He feared that the term "diphtheria" is used to cover a multitude of sins. He did not believe, for example, that the tonsillar diphtheria, as we usually see it is the same disease as the virulent nasal diphtheria which sometimes occurs.

Dr. L. Freeman remarked that the opinion expressed by the last speaker as to the variety of the affections grouped under the designation diphtheria was that held by Löffler, Flügge, and a number of other bacteriologists. Baginsky, in his recent work on *Diseases of Children*, supports this view. These all hold that there are a number of diphtherias, each due to a special microorganism.

Dr. C. W. Tangeman spoke of the occasional occurrence of diphtheria of the conjunctiva, of the eyeball and lids, and stated that a case of this character had come under his observation within the past two weeks. The poison, when attacking the eye, does not manifest always the same degree of virulence, as it sometimes destroys the globe within from thirty-six to forty-eight hours, whereas, at other times, it pursues more of a

chronic course. He expressed disappointment that Dr. Rachford had not advanced anything that might aid us in the prevention of such accidents as the inoculation of the eyeball, or that would cut short the course of the disease when once developed.

DR. J. L. CLEVELAND thought that Dr. Rachford had given us a very valuable hint as to the best means for the prevention of the accidents referred to by the last speaker, when he pointed out the fact that the micro-organism of diphtheria is, in all probability, an external parasite, incapable of existence within the body of man. This, he thought, gave us some hope that we may be able to do something, both for the prevention of the inoculation of external parts of the body, and for the prevention of constitutional manifestations. Most of us are too much in the habit of considering diphtheria a merely constitutional disease from the start, and, although we treat it locally, we do not expect much result. The paper explained another point which had repeatedly been observed by the speaker, and that was the tendency of the disease when seated in the trachea to extend downward. He could not, however, accept the theory that one attack of diphtheria confers immunity from succeeding attacks, as he had repeatedly seen a second, and, in a few instances, a third attack in the same individual. In this respect he thought the popular idea is correct.

DR. G. S. MITCHELL thought there was a good deal of truth in the idea of immunity. A few years ago he had held to the view that diphtheria is a constitutional disease from the start; now he considers it both local and constitutional. He had seen cases in which the redness of the fauces, the pain, and the elevation of temperature preceded by twenty-four to thirty-six hours the exudation in the fauces. He thought it probable that he had, in some instances, done more harm than good in the forcible treatment of children affected with this disease, and that the wedging apart of the teeth and the thrusting of a brush into the fauces were capable of aggravating the constitutional disturbance, He now resorted more to the use of sprays of the benzoate of soda and other alkalies, trusting further to constitutional treatment.

DR. WILLIAM JUDKINS had formerly believed that immunity was conferred by one attack of diphtheria, but he had, within the last eighteen months, abandoned that idea, from the occurrence of a second attack in former patients.

DR. E. E. SATTLER was a firm believer in the local character of diphtheria, and he believed that the disease is diphtheria wherever it is found. In times of cholera, we have mild cases, in which there is only a little diarrhœa; in times of typhoid fever, we have walking cases; and in times of scarlet fever, we meet with very mild cases; so we may have every variety of diphtheria. The variety of the disease may depend upon the amount of poison that is taken into the system, but that is a point on which we know too little to engage in discussion, as we do not know what is the cause of the disease. As regards the ptomaines, it is a question whether the bacilli, which Löffler and Klebs show to be present, may not simply carry the alkaloids which happen to be present into the system, or are, as the essayist asserts, produced by the bacilli at the point of entrance into the system. The speaker thought that, in the majority of instances, tonsillar diphtheria precedes the nasal development of the disease. As regards post-diphtheritic paralysis, he could not agree that it is due to degenerative changes in the nerve-cells or nerve-endings, for, if this were the case, the affection would not so readily yield to treatment.

DR. A. N. ELLIS inquired why, if diphtheria is a local disease, we have a membrane formed on any abrasion which happens to occur in the skin of the patient suffering from the disease. Does not the poison reach the abrasion through the blood-circulation?

DR. JOSEPH RANSOHOFF replied to this that he had seen very many slight wounds in the skin of children suffering from this disease, and that he had not once seen diphtheria develop in them. He had but once seen it follow tracheotomy. In the text-books we read that many cases die of wound diphtheritis. This he thought a peculiar survival of a misstatement. The fact that so many wounds escape infection the speaker held as one of the strongest corroborative evidences of the local character of the disease.

As regards the question of immunity, he did not think that one attack protected the individual from subsequent attacks. Immunity is a quality which belongs to constitutional diseases. It is an attribute of venereal diseases. Syphilis, a constitutional disease, confers immunity, whereas gonorrhœa, a local disease does not. In the light of the paper under discussion, he said that if he had occasion to treat a wound in a diphtheritic subject in the future, he would seal the wound up as tightly as it could be sealed.

DR. T. P. WHITE asked Dr. Rachford to explain how the albuminuria which sometimes follows diphtheria originates. Is it or is it not due to the action of the ptomaines?

DR. DAVID DEBECK said that diphtheritic conjunctivitis always occurs synchronously with the tonsillar or pharyngeal lesions of the disease. It is, however, an affection that is almost never seen in this country. It is as rare as is leprosy. As regards diphtheritic ophthalmoplegias, they support the idea that paralysis occurs more frequently in mild cases. He did not recall an instance of paralysis affecting the eye as a result of a severe attack of diphtheria. They also support the theory that the paralysis is due not to organic, but to functional disturbance, and that the disease is local. The ophthalmic infection in diphtheria is not a direct result of the disease, but is indirect.

DR. GEORGE W. RYAN stated that his experience with post-diphtheritic paralysis had been that it was very amenable to treatment. He looked upon the cases as hardly needing faradization. It is customary to give the patients tonics, and a little massage. This would rather contraindicate the presence of nerve degeneration, or, if such be present, it must be very slight in degree.

DR. WALTER S. CHRISTOPHER, at the request of Dr. Rachford, stated that the gases of the intestinal canal are, for the most part, of a reducing character, that is, directly the opposite of oxidizing. We find that the most prominent gas is carbonic acid gas, which, while it contains some oxygen is not an oxidizing product. Marsh gas is also present, and free hydrogen and also nitrogen to a certain degree, but analysis has failed to show the presence of any oxygen. In a recent experiment of introducing into the intestine a large quantity of oxygen for the purpose of conveying the gas through the portal

circulation to assist the liver in the destruction of ptomaines, and perhaps in certain other of its functions, it was demonstrated that when oxygen comes into contact with the mucous membrane of the intestine, it is taken up into the blood almost as readily as it is absorbed by the capillaries of the lungs, showing that the intestine may perform a respiratory function. This shows us further, that if oxygen is formed or introduced into the intestinal canal it is in all probability readily absorbed. He thought that, in the case of the germs of diphtheria finding lodgement in the intestinal canal, it was probable that they obtained their oxygen from the intestinal wall, just as other germs do. The union between the oxygen and the hæmoglobin in oxy-hæmoglobin, although chemical in its nature, is so feeble as to constitute little more than a mechanical union, very readily disturbed.

Dr. Rachford, in concluding the discussion, stated that it had not been his desire to present anything new or startling in the study of diphtheria. It had rather been his desire to study the testimony in regard to the disease from various sources, and from it to arrive at conclusions not arrived at by others. He had tried to avoid dogmatic statements, and, previous to making any statement, had given the testimony upon which he had based it. The statement which Dr. Stewart has pronounced as dogmatic, had been taken directly from one of the greatest authors of the day, Jacobi, and the argument he had made in that connection had been made solely on the strength of that statement.

He expressed surprise that his statements had met with so much support this evening, inasmuch as they were not orthodox. Few of his conclusions, in fact, were at all orthodox. That the disease is local, is not orthodox; that it is due to a germ, has not been altogether recognized; that the germ is aërobic is not orthodox; that one attack gives temporary immunity, is contrary to the statements of Jacobi, Smith, and other writers. He thought that the varying severity of the constitutional symptoms is best explained as due to the entrance of the germs of decomposition into the blood, not as a part of the disease, but as an accompaniment of it.

The question as to why certain diseases are self-limiting, is a perplexing one. Why is it that any of these self-limiting diseases stop of their own accord? We do not know, and we can only suppose, that some change has taken place which terminates the disease; and it seems reasonable to suppose that the condition which brought about this cessation of the disease would give immunity. And a point which he brought out in the paper was that, therefore, self-limited diseases upon this theoretical ground, must necessarily produce a certain amount of immunity—at least, a temporary immunity—for it is the acquisition of this immunity which terminates the disease. Why is it that the disease does not return again to a former spot in the throat; why does the individual not become re-inoculated after the disease has in part subsided? He was aware that Jacobi, who believes that the patient may become re-inoculated, recommends that the patient be frequently changed from one room to another, in order that he may escape from his own virus; but he did not think that clinical experience will support this theory. Why, too, is it that one little patient running about the room during convalescence will not be re-infected from his brother, who is going through an attack subsequent to his?

Yet, there is reason to believe that the immunity does not exist for any great length of time. It may last for one, two, or three years, owing to the severity of the constitutional symptoms. If the throat has been left in an inflamed and irritated condition by the disease, so that there is a favorable soil for the lodgement of germs, then the previous attack will predispose to a second. This, he stated, was most likely to occur in individuals in ill health, scrofulous, tuberculous persons.

As to the explanation of kidney trouble, the speaker referred to the fact that certain chemical reagents, when introduced into the body, will bring about very marked changes, fatty degeneration, etc., and various other changes, such as we find in the kidneys. The microscope does not reveal these agents. It is not in every case of albuminuria that we find microörganisms. The testimony of the microscope is not, therefore, of much value. As albuminuria is not necessarily due to the entrance of germs, that which follows diphtheria may have an entirely different origin.

In regard to the asserted presence of degenerative changes in the nerves as a cause of the post-diphtheritic paralysis, the essayist did not agree with the previous speakers that such degeneration would necessarily argue an unfavorable prognosis. On the contrary, Welch, in his Cartwright lecture, shows that fatty degenerations in the liver, kidneys, and other organs result from fever. He further shows that these degenerations rapidly disappear after the subsidence of the fever. The speaker saw no reason that the degenerative processes which develop during the course of diphtheria as a result of the direct action of ptomaines, might not as rapidly disappear upon the subsidence of the cause. It is not rational to suppose that a soluble alkaloid will remain in a body six, eight, or ten weeks after the disease has subsided, and then produce a paralysis. It is, however, reasonable to suppose that the ptomaines may have acted in such a way as to produce a slight change, to set up a certain degenerative process, but not to such an extent as to produce paralysis; but afterward, on account of the low condition of the body, on account of the leucocythæmic condition of the blood, and the low condition of the patient generally, this degeneration will continue until, four, five, or six weeks after the attack, paralysis will be produced. The arguments against this view by J. Lewis Smith are those presented in the paper, namely, that the paralyses are frequently degenerative, and may occur early. These cases are not those which occur after the attack, but those which occur during the attack, and are a result of the direct action of the ptomaines.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 17, 1889.

The President, A. Jacobi, M.D., in the Chair.

Dr. Paul Gibier, Assistant to the Chair of Pathology of the Museum of Paris, read a paper on

YELLOW FEVER: AN EXPERIMENTAL RESEARCH ON ITS ETIOLOGY.

(See The Medical News, January 26, page 91.)

DR. L. DUNCAN BULKLEY then read a paper on

UNUSUAL METHODS OF ACQUIRING SYPHILIS, WITH REPORTS OF CASES

(which will appear in full at an early date in THE MEDICAL NEWS).

SAMUEL T. HUBBARD asked whether, in Dr. Bulkley's opinion, syphilis could be conveyed to a sucking infant through the milk of the nurse when the latter, so far as could be made out, was entirely free from any lesion of the disease. A case which he believed to be of this kind, in which there was apparently no other source of infection, had occurred under his observation.

DR. BULKLEY replied that two observers had made experiments with the injection of milk from syphilitic women, and while one claimed that syphilitic infection was thus conveyed, the other met with negative results. At the present day most writers are inclined to deny that the disease could be transmitted by milk alone, and hold that when this was apparently the case, the infection was really carried by some secretion associated with it.

THE PRESIDENT, DR. H. JACOBI, said that there was one circumstance which might explain how, under certain conditions, the milk might be the means of transmitting syphilis. There was some milk which might be capable of doing so, and some which was not. In the perfectly healthy woman milk was a true secretion, made in the mammæ, and not a transfusion from the blood. There were, however, a number of conditions in which the milk was in a large measure simply a transudation. In anæmic or convalescent women, or in those reduced in strength by prolonged nursing, the milk changed its character, and the mamma became for the most part a filter, through which was transmitted the serum of the blood and whatever might be floating in the blood. Thus, when the nursing woman was healthy, medicines would not be transferred through the milk to the child, while if her system became reduced from any cause, lead, iron, iodide of potassium, and other drugs would be thus conveyed. From these facts, therefore, he could not doubt that under similar circumstances it was possible that syphilis could be transmitted by means of the milk.

SECTION ON THEORY AND PRACTICE OF MEDICINE,

R. C. M. PAGE, M.D., CHAIRMAN.

Stated Meeting, January 15, 1889.

ELECTION OF OFFICERS.

DR. R. C. M. PAGE was elected *Chairman*, and DR. G. R. ELLIOTT, *Secretary*, for the ensuing year.

DR. SCHUMAN LE CLERCQ, of Carlsbad, Austria, read a paper on

THE INFLUENCE OF CARLSBAD WATER ON URIC ACID EXCRETION.

The beneficial effects of the "Carlsbad cure" in gout, he said, had been recognized by the profession for centuries past, but the theoretical grounds upon which an indication for this treatment might be based had been as vague as the theory of gout itself. Prof. Seegen was the first to establish a positive theory to explain the action of the water. From his investigations he concluded that it caused a diminished nitrogenous metamorphosis and a decrease amounting to practical disappearance of uric acid; and it was generally believed that the effect of the Carlsbad water in gout depended upon its power to counteract the increased conversion of nitrogen inherited or acquired by high living; this being the conception of the pathogenesis of gout which prevailed at that time. Prof. Voit, detecting the sources of error which led Seegen to his incorrect conclusions, definitely refuted the theory of a lessened organic metamorphosis from the use of Carlsbad water, and the extensive discussion which then arose ought, he thought, to be considered as having settled this question; so that a recent attempt to revise it was undoubtedly a mistake.

As to the second point, the gradually diminished elimination of uric acid, Dr. Le Clercq said that he had been unable to find any account of further investigation, and Seegen's opinion continued to be accepted in the treatises on bacteriology and gout. At the suggestion of Dr. Hermann, of Carlsbad, he made a series of careful experiments upon his own person with the view of ascertaining whether the diminution of uric acid excretion under the influence of Carlsbad water, as claimed by Seegen, could be proved by our recent exact methods of quantitative analogies for uric acid. He made use of a method recently advocated by Prof. Haycraft, of Aberdeen, slightly modified by Dr. Hermann, and combated by him with Ludwig's method, and the analyses were made at Prof. Huppert's laboratory at the University of Prague. Haycraft's method was essentially as follows: By adding to the urine bicarbonate of soda and a solution of silver nitrate, previously rendered ammoniacal, a white gelatinous precipitate of urate of silver (and of phosphates) is obtained, which will not be reduced before it can be collected and washed on a felt-like filter compound of asbestos and broken glass. The ready solubility in nitric acid of this urate-precipitate is used for estimating the silver by Volhard's method, and we then calculate the uric acid by its combination with silver.

The experiments were continued from September 19 to October 20. Having analyzed his daily amount of uric acid for five days, while placed upon a regulated diet and mode of life corresponding to that of Carlsbad patients, he took Carlsbad water every day in gradually increasing quantities, and determined the amount of uric acid excreted during each twenty-four hours. One hundred grammes of urine were used for two parallel tests. A table containing the results of his investigations showed that the daily amount of uric acid was, upon the whole, unaltered by the use of Carlsbad water. The quantity remained between 80 and 108 centigrammes a day, and the total amount executed in a period of five consecutive days varied only between 4.023 and 4.890 grammes. During the time that the experiments were carried on, he lost 2950 grammes in weight.

Dr. Le Clercq had arranged in a table a *résumé* of the results of the experimental researches of different authors with regard to the influence of various agents on the excretion of uric acid. In connection with it he called attention to the great difference of opinion existing on every point, which showed that as yet no definite conclusions could be reached on this subject. Many of the analyses were made with inaccurate chemical methods, and all the tests were not made with the urine of twenty-four hours; while the series of experiments, with a few exceptions, were not long enough to yield results that could be compared. The increase or decrease of uric

acid was not necessarily due to any extraneous factor, as claimed, since similar fluctuations were also observed under normal conditions. The latter fact was illustrated in the experiments on himself. Although he was most careful in regard to every detail, he could not at times avoid considerable variations in the uric acid excretion any more than other observers; although he admitted that some of them were more fortunate than himself in this regard. This variation in the amount of uric acid was all the more striking in his own case, since by his strict adherence to a uniform diet and mode of life, every possible source of variation, in so far as the excretion of uric acid was concerned, was thoroughly excluded, and certainly, if any effects of the Carlsbad were demonstrable, every opportunity was afforded for their exhibition. It was to be remembered, however, that, according to Newbauer, the amount of uric acid, unlike urea, depended less on the food eaten than on special internal conditions of the organism, and that it varied greatly even in the normal state. Lehmann's tests on his own person also pointed to the fact that the nature of the food influences the excretion of uric acid much less than that of urea.

Since, therefore, no external causes could influence the daily variations in his uric acid excretion, he could only ascribe them to internal causes, such as a regulating nervous influence. In fact, there were authors who attributed the final regulation of uric acid production and excretion to the nervous system. According to Latham, gout was caused by a disturbance of the vasomotor centre, which influences the processes of organic metamorphosis, particularly in the nervous system. The atypical formation of uric acid in the muscles in gout, as accepted by Ebstein, could be considered from the same standpoint. While Garrod's thread experiment favored an idea of an excess of uric acid in the blood of the subject of gout, and though he himself afforded the experimental proof that uric acid is the "materia peccans," Eberstein did not consider it necessary to accept a general accumulation of uric acid, at least for the primary form of articular gout, because a localized retention of uric acid or a formation of uric acid in a *wrong place* (independent of increased production), could satisfactorily explain the development of gouty symptoms. Moreover, though it was universally agreed that in leucæmia there are increased formation and excretion of uric acid, this disease was never combined with gout, for which we must assume a disposition for a weaker resistance of certain organs against uric acid, either inherited or acquired. All this, he said, fully proved that the indication afforded by the secretion of uric acid cannot always be taken as an index of the quantity formed in the system (Garrod), and that the beneficial influences of a remedy in the uric acid diathesis cannot possibly be proved by analysis of the urine.

Although his experiments were made on a healthy individual, the same conditions as noted above would undoubtedly prevail in gouty patients. If, however, experiments were made on the latter under the same conditions, the question would inevitably present still greater difficulties, as the particular plan of the disease present in any case would add still greater complications to the results. For these reasons he was inclined to believe that in the future the influence of a medicinal agent on the increase or decrease of the uric acid excretion would not be conclusive as regards its indication or contra-indication in gout.

From a general review of the results obtained in his experiments he felt compelled to say that a decrease of uric acid excretion under the influence of the Carlsbad mineral waters, as accepted by Seegen, does not appear if the lists are controlled by the recent analytical methods, which secure a much more accurate result than the method of weighing uric acid after precipitation by hydrochloric acid, as employed by Seegen. Thus, the results of the experimental investigations on which it had been customary to explain the remarkable action of Carlsbad water in the treatment of gout proved untenable on repetition of the experiments when controlled by modern methods. This was now, perhaps, of less importance, however, as the ideas which formerly prevailed concerning the nature of gout were also undergoing a complete revolution, and one which would yet require much work before everything was made clear. At all events, the experiments which up to the present time so satisfactorily proved the therapeutical action of the water must now be considered insufficient.

Referring to those general physiological and pathological principles which might enable us to understand more readily the facts of practical experience, Dr. Le Clercq said that he noticed first in gouty patients under the Carlsbad treatment an amelioration of those symptoms which were explained as being occasioned by the presence of the "materia peccans," whether excessive or not, in the blood or organs. It was often seen, for instance, that albuminuria, inflammations—renal, pelvic—migraine, and nervous troubles, such as hypochondria, melancholia, and hysteria, became improved or disappeared. According to the accepted view, he explained these complications as being due to excessive quantities of uric acid dissolved in the blood; and hence he believed that by the imbibing of the warm alkaline water, which becomes so rapidly diffused in the blood, the conditions for a prompt discharge were rendered more favorable, and the diluted urine, which soon became alkaline, in a short time removed the surplus of uric acid circulating in the blood.

But he also saw, in the second place, that the gouty attacks, formerly frequent, were kept off for some time, or became less intense, or, perhaps, ceased altogether, after a course with the water. With regard to this therapeutical effect, he could not be satisfied with the former explanation of a "washing out," but had to acknowledge that the cause of the disease, the diathesis, seemed mitigated. While not attempting at present to explain this fact, he could only say that since Minkowski's researches the liver was known to have a third function besides gall secretion and glycogen-formation, viz., the sympathetic formation of uric acid. We know that sulphate of soda, so plentiful in Carlsbad water, considerably stimulated the gall-secretion, and it seemed probable that the salt also affected the uric acid formation. But, aside from the question of an excess of uric acid in gout, whether localized or general, he had in this disease an anomaly in organic metamorphosis which was undoubtedly a complicated process. Such anomalies had derived benefit from the Carlsbad treatment, and he was inclined to ascribe this to the great improvement in the general condition caused by the latter. As the food was so important a factor in the group of disorders embracing diabetes, adiposity, gout,

oxaluria, pyrocatechinuria, and cystinuria, we might justly ask whether a faulty digestion in the stomach cannot promote the gouty process under certain unknown conditions by the absorption of abnormal products of the food. Wine, for instance, had no influence on the increase or decrease of uric acid formation; yet many close observers attributed in certain cases a sudden attack of gout (and with apparent justice) to a single imprudent use of wine. This, he thought, could only be explained by the well-established fact that alcohol has a direct protracting, and thus pathological influence upon the digestion of the stomach. In the same way he could explain by its direct typical action in the stomach and liver the recognized beneficial effect of Carlsbad water in many phases and forms of gout. According to Garrod, the mineral waters were indicated in gout for the reason that the diathesis leading to its production was often closely connected with deranged hepatic formation, and Ebstein and others recommended them particularly in those forms of gout complicated with plethora or gastric symptoms.

The compound action of Carlsbad water, Dr. Le Clercq said, arose, in the first place, from the influence of the warm water itself, which, when absorbed in large quantities, as Garrod had remarked, powerfully stimulated the processes of the animal economy. and increased the various secretions. Secondly, from the salts contained in it. Sulphate of soda produced increased peristalsis and excretion of water, urine, and urea. The cathartic action cut short, so to speak, complete digestion and absorption of the ingesta, and excretory matters, which would otherwise be retained, were quickly eliminated. Chloride of sodium greatly excited the stomach's functions, and induced increase of urine and nitrogenous excretion, while carbonate of soda improved the digestive power of the stomach, and increased peristalsis and the natural alkalinity of the blood. If now, by virtue of the properties of the constituents of the water, there was an increase of peristalsis and diuresis, and an increased flow of liquids in the tissues, while, with less food, plenty of outdoor exercise and baths were taken, fewer products of retrograde metamorphosis would circulate in the blood and organs; and those which did circulate would be more easily eliminated. Finally, not only were the secretions increased by Carlsbad water, but also the pressure under which they were secreted; this effect being due to taking the water in sips. The latter was probably the result of nervous influence, for Kronecker had shown that a liquid taken in many small sips would, for the time, completely abolish the inhibitory action of the vagus of the heart. This consideration would assist in explaining how certain predispositions of tissues, like cartilage, to receive injuries in gout might be effectually combated by means of Carlsbad water. The increased pressure referred to would be beneficial by increasing the *vis à tergo* in such organs as had a torpid tissue change, owing to the absence or scanty supply of bloodvessels. The nutrititve liquid being now more easily renewed, the conditions were not favorable for a deposit of urates.

The Carlsbad cure, which combined other factors, such as bathing, diet, and exercise, in addition to the water, had been thoroughly studied in a paper read by the Chairman, Dr. Page, before this body, and he said that he would refer his hearers to that for details. The hot baths, in particular, were useful by increasing the activity of the circulation and respiration, and increased consumption of oxygen and exhalation of carbonic acid would cause conversion of fat (so of the superabundant in gout), and decomposition of the constituents of the body containing nitrogen, with corresponding increase of urea in the urine.

As contraindicating the Carlsbad treatment in gout Dr. Le Clercq mentioned those advanced stages of the disease with serious structural implication of the kidneys, or in which cachexia has resulted (aside from such other general pathological conditions as contraindicate the treatment, like cardiac diseases, pronounced anæmia, carcinoma, and phthisis). If, as Garrod claimed, the causes exciting an attack of gout, were those which induce a less alkaline condition of the blood, or which temporarily check the eliminating power of the kidneys, the properties of the alkaline and diuretic Carlsbad water fully established its prophylactic value.

DR. FESSENDEN N. OTIS said he had listened with great pleasure and interest to the scientific exposition of the character of the Carlsbad water as set forth in the paper by Dr. Le Clercq, and that he had rose more particularly to say something of his own impressions concerning its therapeutic value as received from a course of treatment in his own person at Carlsbad during the past summer, from his observations of the effects of the water on the different classes of cases which he had seen there, and from the results obtained from it in various patients which he had sent to Carlsbad in previous years.

He had been in the habit of assuming for a long time past from what he had noticed of the Carlsbad cure that patients suffering from troubles due to functional obstruction of the liver and those with uncomfortable accumulations of adipose tissue were most likely to be benefited by it; and his experience with regard to it in those conditions had been exceedingly gratifying. In those suffering from biliary calculus the action of the water was very prompt and efficient, and, as far as he had been able to observe, its use was attended with permanent benefit. Cases under his care, in which all the ordinary methods of treatment failed, had, after a course at Carlsbad, been entirely relieved. It was usually advisable, however, for such patients to spend two or three consecutive seasons there. In two or three such cases that he recalled there had been no return of the attacks after the lapse of four or five years.

Dr. Otis described, with considerable detail, the case of a gentleman sixty-five years of age, suffering from aggravated liver trouble, the result of high living, whose condition, notwithstanding the fact that for two years he had been most abstemious in his habits, and in spite of all treatment gradually became worse and worse, until he was taken, in a very weak state, to Carlsbad, when he immediately began to improve. At the present time, at the age of sixty-nine or seventy, he is apparently one of the healthiest men in the city of New York; and so decided were the effects of the Carlsbad treatment that since taking it he had been able to resume habits of life that were simply astonishing in a person of his age. The same results, he said, had been seen in repeated instances under his observation.

That which decided him to try the Carlsbad treatment in his own person was the existence of gout and what he supposed to be gouty dyspepsia, which was attended with more or less mental hebetude and an inability to attend properly to his usual professional work. While

at Carlsbad he daily took, at short intervals in the morning, five seven-ounce glasses of the water, at a temperature not exceeding 80° Fahrenheit, drinking it in sips. The regimen to which he was subjected involved the avoidance of starchy food, but allowed a sufficient amount of nourishing diet; and he took two glasses of claret a day. Although taking only a very moderate amount of exercise, he lost one pound a day for thirty days, and among the results produced by the treatment was a considerable loss of strength. He experienced more or less debility for a month after leaving Carlsbad, spent principally in Switzerland; but he gradually improved in flesh and strength, and at the present time he enjoyed an amount of freedom from dyspeptic trouble which he had not had for a number of years. His own experience was also that of a good many other individuals with whose cases he was well acquainted.

Aside from the diet and the regular habits imposed upon those taking the treatment at Carlsbad, he believed, therefore, that there was something in the water which tended to the elimination of effete material from the system. This is what is needed in the class of cases under consideration, and, in general, he had found that those remedies which produced this result were the most valuable. Thus, mercurials were of very great service, and patients with the uric acid diathesis were immediately benefited by their regular administration. In such cases from one to three grains of calomel a day could be taken for a considerable time with great advantage, and without producing any deleterious results.

THE CHAIRMAN said that individuals who had too much fat, and those who had an excess of uric acid, would derive the greatest possible benefit from the course at Carlsbad; but for those suffering from Bright's disease or pulmonary trouble, or from any grave depression of vitality, it was only attended with evil. He had, however, expressed his views on this subject very fully in a paper published in the *Medical Record*, in October, 1886, and would not go into any details on the present occasion.

SECTION ON ORTHOPŒDIC SURGERY.

LEWIS A. SAYRE, M.D., CHAIRMAN.

Stated Meeting, January 18, 1889.

DR. H. B. JUDSON read a paper on

THE QUESTION OF INTERFERENCE WITH THE ABSCESSES OF HIP DISEASE.

He exhibited two cases of hip disease in which abscesses had been absorbed with most favorable results, locally and generally, and thus introduced a defence of the expectant plan of managing such abscesses which, he said, he had followed for many years. He believed that if mechanical and hygienic attention is duly paid to the affection of the bone and joint, the abscesses, if they occur, will be best managed, as a general rule, by allowing them to become absorbed, or to open spontaneously. Their presence does not add to the gravity of the deep-seated bone disease, or interfere with the natural repair and cicatrization of the osseous tissue involved. Many such abscesses are cold and painless, and attain a large size. Their rupture is also painless, and is followed by an unimportant scar. In two of his cases the rupture occurred during sleep, and the patients supposed they had wet the bed.

Many cases, however, are phlegmonous, and attended with pain and general wasting. He would here advise (1) absolute rest to the joint, (2) the most generous and varied diet, and (3) the use of opium in potent doses, if required. He believed that incision is a tardy and fruitless procedure, because the most painful stage is present when the pus is in the cells below the periosteum. It substitutes artificial for natural closure, and, even with the best antisepsis, is useless in many cases unless followed by scraping of the purulent depôt, excavation of the focus, or excision. It is difficult for the general surgeon, or the beginner in orthopœdic practice, to refrain from operating in such cases, but it takes but little knowledge of the way in which the abscesses of hip disease are treated at the present time, to see that the general surgeon, whose reliance is chiefly on operative procedures, resorts to the knife with the hope of promoting a rapid recovery; while the orthopœdic surgeon, who relies chiefly on mechanical means, seeing that the case, no matter how treated, will be tedious, devotes himself to the proper management of the bone disease, and thinks but lightly of the incidental abscesses.

MONTREAL MEDICO-CHIRURGICAL SOCIETY.

Stated Meeting, January 11, 1889.

THE PRESIDENT, WM. GARDNER, M.D., IN THE CHAIR.

DR. WM. GARDNER exhibited a specimen of

PAPILLOMA OF THE OVARY.

The patient was aged sixty and married, never pregnant, had suffered for many years from prolapsus uteri, but otherwise had been healthy until a year ago, when she first noticed a lump in the abdomen. This slowly increased and became so painful that for several months she had taken morphia regularly. From being a very stout individual she had become very thin. When the patient came for operation, she was found to have a very severe cough with effusion in the right pleura. This, however, soon disappeared and operation was performed for the removal of the tumor. On opening the abdomen no adhesions were found, but there was a considerable quantity of straw-colored peritoneal fluid. The pedicle was most favorable. The growth was confined to the ovary; the whole growth, with the exception of one small cyst, was solid and had a sarcomatous appearance. It was about the size of a child's head. The case made a rapid recovery. The peritoneum was drained with a glass tube for several days. The tumor was examined by Dr. Lafleur and found to be papillomatous.

DR. GARDNER also reported a case of

DOUBLE TUBERCULAR PYOSALPINX.

The patient was aged twenty-nine years, had been married five years, and had been pregnant twice, but had only gone to full term with her last child, which had to be delivered with forceps; since then she "has not seen a well day." Has had repeated attacks of inflammation, confining her to bed six and eight weeks at a time. There was constant pelvic pain, profuse hemorrhages, and very painful menstruation. Notwithstanding this she was very fat, though flabby and anæmic. The tubes which had been removed were shown; both

were dilated to the size of sausages and filled with pus, the inner surface showing numerous miliary tubercles. There was no evidence of tubercle elsewhere. The patient made a somewhat tedious recovery.

Dr. Gardner remarked that at a meeting of the British Gynecological Society, on the 13th of June last, Mr. Lawson Tait had exhibited tubercular pus-filled tubes from a patient who also had an extra-peritoneal cyst. This patient and another affected similarly, recovered.

DR. ALLOWAY said he was much interested in Dr. Gardner's specimen of tubercular tubes, especially as he had been present at the operation. When the tubes were first seen, it seemed as if the disease was confined to the abdominal end. The tubes were hard, thickened, and apparently only fluctuated toward their abdominal extremities. The isthmus was healthy in appearance and when cut across did not exude pus. From this it would appear that the disease originally began in the tubes and was not an extension from the uterus. In pyosalpinx the origin could be traced either to a past attack of septic endometritis following delivery at term, to an abortion, or to leucorrhœa. In the case under discussion it was perfectly clear the disease did not spread from the uterus but must have originated in the tubes themselves. Dr. Alloway also stated that it was very rare to find tubercle in the tubes of women who had been marrried for some years and who had borne children; the disease was usually found in young virgins who were of a tubercular diathesis and who probably in time would have developed similar disease in the lungs or elsewhere. He did not think tubercular pyosalpinx influenced the nutrition of the patient.

Dr. Mills said that pigeons after the breeding period and during moulting frequently died of tubercular disease of the oviducts, the disease being very apt to attack weakened organs. The tubercle was usually caseating and there was no tubercle elsewhere.

DR. BELL said it was not the usual experience for the patient to increase in weight when suffering from tuberculous disease. He doubted the tuberculous nature of the case.

DR. LAFLEUR said that when tubercle was localized in the lungs, or other vital organs, it interfered with important processes, such as oxygenation of the blood, etc., hence the wasting; but when a remote organ like the ovary was attacked, nutrition would not necessarily be interfered with.

DR. RODDICK remembered many cases of tuberculous testicle in apparently healthy people, and in them the disease had had no perceptible influence on nutrition.

DR. GARDNER then exhibited the specimens from a case of

HYDROSALPINX OF RIGHT SIDE, WITH SMALL CIRRHOTIC OVARIES.

The patient, a poor woman, aged thirty-nine years had spent the last two years between the hospital and a home for friendless women, suffering almost constantly from pain in the right iliac region and right side of the trunk, generally with great distress in the epigastric region. Her appetite was small, and vomiting was frequent. As the uterus was retroverted it was sutured through each broad ligament to the anterior abdominal wall. The operation for removal of the appendages presented no difficulties. The patient made a good recovery.

DR. LAFLEUR exhibited for Dr. Ross an

ANEURISM OF THE ASCENDING AORTIC ARCH.

The aneurismal dilatation involved the aorta from the semilunar valve to the middle of the transverse arch. There was no distinct sac, the whole of the vessel between these two points being uniformly dilated. No adherent laminated clot was found within, but merely a small post-mortem fibrinous clot. The inner surface of the wall of the aneurism was roughened by numerous glistening firm raised grayish-yellow atheromatous patches. There was very slight inflammatory thickening of the aorta. There was slight incompetence of the aortic valve due to dilatation of the orifice. The aneurism did not reach the thoracic wall, being prevented from doing so by an adhesion of the whole anterior border of the right lung to the parietal pleura. This circumstance would account for the absence of absolute physical signs in that situation. From the main dilatation of the aorta there was a small secondary sacculated aneurismal dilatation, situated immediately in front of the trachea immediately above its bifurcation. This sac measured one and a half inches, and could be seen on the tracheal surface as a convex ovoid projection, which, in the natural state, must have caused nearly complete occlusion of the orifice of the left bronchus. Over this prominence the mucous membrane was inflamed, and through it could be felt the eroded cartilage rings of the trachea, the tracheal cord being almost perforated. The immediate cause of death was a double broncho-pneumonia involving the lower lobes of both lungs.

DR. RODDICK presented a stone removed by the

SUPRAPUBIC OPERATION.

The patient was a man, aged seventy-six years, who had suffered from symptoms of stone for nine years, and who had, on several occasions, passed calculi; latterly he suffered great pain, and insisted on operation, although in a very feeble condition. On the first introduction of the sound the stone was discovered, and as it was made out to be of large size, the suprapubic operation was chosen. The operation was performed, and the stone, which weighed four ounces, easily extracted; the bladder was not sutured, but a drainage tube was inserted, and the bladder was also drained by a catheter introduced through the penis. The patient died of exhaustion on the fourth day. There was no fever, and the wound was always healthy looking.

CORRESPONDENCE.

THE ORIGIN OF THE FLORIDA YELLOW FEVER EPIDEMIC.

To the Editor of THE MEDICAL NEWS,

SIR: An article in THE MEDICAL NEWS of the 5th instant, relating to the origin of the yellow fever epidemic in Florida has been brought to my attention. The statement that the man Turk was an Italian I long ago corrected, but my impression still is that he brought the fever to Tampa. The evidence is now in the hands of the Senate Committee, and will doubtless be printed in due course. My statements being based on information and not on actual observation are, of course, liable to correction when proof is furnished to the contrary, but it

will take something more than an affidavit to convince me that Turk did not visit Key West during the epidemic. A singular corroboration of the original statement is found in the affidavit that he is alleged to have accompanied Pepe in the "hunting expedition." Was this "hunt" in the direction of Punta Gorda Bay? If so, that is all that was claimed. However, my authority for the statement was long ago sent to the Senate, where it now remains. I am very truly yours,

JOHN B. HAMILTON.

CHICAGO, January 21, 1889.

NEW INVENTIONS.

A NEW INSTRUMENT FOR THE EXTRACTION OF A DISLOCATED LENS.

BY H. F. HANSELL, M.D.,
OF PHILADELPHIA.

THIS instrument was devised for the removal of a lens which had been traumatically dislocated behind the iris, and answered the purpose so admirably that it may be worthy of being brought to the notice of the profession.

The accompanying cut represents double the size of the extractor. It is made of soft metal, has three prongs,

each of which is armed at its extremity with a fine barb; its breadth is 4 mm., length 8 mm., and each barb 1 mm. in length.

The operation necessary, briefly described, is:

1. Linear or modified linear cut, as in Graefe's extraction of cataract.

2. Iridectomy (this should be done if the lens is normal or nearly normal in size).

3. Introduction of the extractor immediately behind the lens to a point below the centre of the posterior surface.

4. Extraction.

This instrument has the following advantages:

1. It will remove a lens equally well with or without its capsule.

2. Its insertion necessitates no displacement or other disturbance of the vitreous in the removal of a lens dislocated behind the iris.

3. Both shank and fork being malleable, the instrument is available in all cases where the lens can be seen.

This instrument is made by E. A. Yarnall, 1020 Walnut Street, Philadelphia.

NEWS ITEMS.

The Royal College of Surgeons and Sir Morell Mackenzie.—At the quarterly meeting of the Council of the Royal College of Surgeons of England, held January 10th, the following resolution, offered by the senior Vice-President, was adopted by a vote of 21 to 2 against:

"The attention of the Council of the Royal College of Surgeons of England has been called to a volume published by Sir Morell Mackenzie, which bears the title, 'The Fatal Illness of Frederick the Noble,' and the Council consider it to be their duty to express their deep regret that any member of the College should have allowed himself to publish in such a manner the charges that are therein made against distinguished surgeons who were his colleagues in the case. The Council have not sufficient means of forming a conclusive judgment on the facts which are in dispute, but in their opinion no provocation, such as Sir Morell Mackenzie alleges, can justify this publication or the language employed in it."

Simple Test for the Detection of Pus in the Urine.—Drop into the specimen of urine enough tincture of guaiac to give it a milky appearance, and heat it to 100° F. If pus be present, a blue tint will develop. The urine may also be passed through a white filter, and a few minims of the tincture of guaiac then allowed to drop on it; if pus be present, a distinct blue coloration will be produced.—*Pharmaceutical Era.*

A New Method of Illuminating Internal Organs.—The well-known experiment for showing total reflection of light in a jet of water or in a glass rod has been made use of here by Dr. Roth and Professor Reuss in devising a new method of illuminating from outside some cavities of the body, such as the larynx and nose. The instrument used for this purpose is a well-polished (not blackened) glass rod, to one end of which a small electric incandescent glow lamp, like those used for electric breast pins, is attached. The light of the lamp is reflected equally through the whole glass rod to its other end, which is placed on the skin of the throat in the case of a laryngoscopical examination being required. Then the interior of the larynx becomes illuminated sufficiently for laryngoscopy. If this luminous glass rod is applied to the sclerotic, the interior of the eyeball can be examined in the same way as by using an ophthalmoscope, the structure of the posterior parts of the vitreous body being very well seen and studied. As the glass rod remains cold, it can be employed in operative surgery to light the natural and artificial cavities.—*Lancet*, January 5, 1889.

Sterilized Milk.—From a correspondence in the pages of the *St. Petersburger medicinische Wochenschrift*, we learn that the practice of sterilizing milk is extensively carried out in the Russian capital, not only in the Children's Hospital and some of the larger dairies, but in many of the private families. Though but recently suggested by the German chemist Soxhlet, whose name is familiar to all analysts through his ingenious apparatus for the extraction of fats, the process is nothing more or less than the common one of sterilizing fluids in flasks by heating them in a water bath to boiling and hermetically closing their mouths while their contents are in a state of ebullition. There has been much discussion both in the papers and in the Medical Society, as to the respective advantages of the flasks advocated by Dr. Gräbner, and the ordinary bottles which Dr. Martenson has adopted after a trial of several special forms. Bottles, he very reasonably urges, are always at hand; they are less easily upset, and less fragile than the flasks commonly used in laboratories, while flasks of thicker glass are liable to break if the heat be applied too quickly.

The best method of closing the flasks or bottles has also been a matter of debate; Dr. Westphalen, of the Children's Hospital, rejects India-rubber stoppers as unnecessary, and Dr. Martenson agrees with him; but corks

are certainly hard to maintain in an aseptic condition. We should be inclined to recommend the new patent spring stopper which has recently been largely employed by wholesale druggists as perfectly air-tight and cleanly, and at the same time, more easily removed than glass stoppers, which are apt to be firmly retained by atmospheric pressure over a partial vacuum. For the rest, a water bath, with suitable arrangements for heating and a rack or frame for keeping the bottles in position, are all that are required.

In the presence of foot-and-mouth disease, which, as Johne has shown, may be communicated as such to man, and has led, more often perhaps than is known, to epidemics, as it were, of low and even fatal pneumonia, with herpetic eczematous eruptions among infants, and indeed in all cases in which the milk in not above suspicion, simple boiling is all that is required to exclude the chance of infection; but in the closure of the bottles while boiling, the subsequent access of aërial germs is prevented, and the milk remains perfectly fresh and unaltered for two or three weeks. Such sterilized milk might be supplied by the dairy companies in pint, quart, or gallon bottles with spring stoppers for use in nurseries, and on board passenger steamships and yachts, where it would be preferred to condensed milk by most persons.—*British Medical Journal*, December 8, 1888.

Naphtha Poisoning in Rubber Factories.—In several large factories in Germany, especially in India-rubber factories and establishments for cleaning India-rubber, peculiar morbid symptoms have lately been observed. The faces of many of the girls, who had not left the factory during the day, became flushed and swollen in the evening, and they could not walk steadily. An examination of their clothes and of the work-rooms for brandy, opium, etc., yielded no result, till an accident lead to the solution of the mystery. In these factories naphtha is used in large quantities, and kept in special boilers closed against the air. The girls had succeeded in getting keys to the boiler valves, and, soon learning the intoxicating effect of naphtha, were in the habit of slinking unobserved to the reservoirs to inhale the poison, which threw them into a state of happy forgetfulness and conjured up a thousand sweet dreams of wealth, splendor, happiness, etc. The secret was revealed by a novice, who made too deep an inhalation and fell into hysterical convulsions.—*Lancet*, January 5, 1889.

The Disinfection of Instruments.—DR. DAVIDSOHN (*Berl. klin. Wochenschr.*, 1888, No. 35), after numerous experiments made at Berlin's Hygienic Institute, comes to the conclusion that instruments are best disinfected by immersing them in water at 212°, and allowing them to boil therein for five minutes. All pathological micro-organisms are thereby destroyed, without any injury being done to the instruments.—*Therapeutische Monatshefte*, Jan. 1889.

Who Owns the Dead Body?—The Medical Society of London discussed this question incidentally at a recent meeting, upon the point whether it was legally possible for a dying person to direct the disposition of his body so as to bind his executors or other representatives. The law at present seems to be admitted to be that no such directions given by will are legally binding, and that, even if the testator leaves money for the special purpose of carrying out his directions, the executors are not bound to apply it in the way directed.—*Medical Press*, December 19, 1888.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 15 TO JANUARY 28, 1889.

LORING, L. Y., *Major and Surgeon*—Is granted leave of absence for one month, on surgeon's certificate of disability—Par. 1, *S. O. 6, Headquarters Department of Arizona, Los Angeles, California*, January 18, 1889.

PRICE, CURTIS E., *Captain and Assistant Surgeon.*—Leave of absence granted in S. O. 257, A. G. O., November 3, 1888, is extended two months.—Par. 1, *S. O. 21, A. G O.*, January 25, 1889.

By direction of the President, and in accordance with Section 1246, Revised Statutes, an Army Retiring Board is appointed to meet in this city, at 11 o'clock A.M., Thursday, the 17th day of January, 1889, for the examination of such officers as may be ordered before it. Detail for the Board: JEDEDIAH H. BAXTER, *Colonel and Chief Medical Purveyor*, and CHARLES R. GREENLEAF, *Major and Surgeon* (U. S. Army).—Par. 2, *S. O. 12, A. G. O., Washington*, January 15, 1889

ALDEN, CHARLES H., *Lieutenant-Colonel and Surgeon*—Detailed for duty on Army Retiring Board, to meet at St. Paul, Minn., at the call of the president thereof.—Par. 7, *S. O. 16, A. G. O., Washington*, January 12, 1889.

EDGAR A. MEARNS, *Captain and Assistant Surgeon* (U. S. Army)—Detailed for duty on Army Retiring Board, to meet at St. Paul, Minn., at the call of the president thereof.—Par. 7, *S. O. 10, A. G. O., Washington*, January 12, 1889.

By direction of the Secretary of War, BENJAMIN MUNDAY, *Captain and Assistant Surgeon*, is relieved from duty at Fort Sisseton, Dakota, and will report in person to the commanding officer Fort Sully, Dakota, for duty at that post.—Par. 2, *S. O. 11, A. G. O., Washington*, January 14, 1889.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE FIVE WEEKS ENDING JANUARY 26, 1889.

CARTER, H. R, *Passed Assistant Surgeon.*—Leave of absence extended six days, December 29, 1888

WHEELER, W. A., *Passed Assistant Surgeon.*—When relieved at Buffalo, New York, to proceed to Cleveland, Ohio, and assume charge of the Service, January 3, 1889.

URQUHART, F. M., *Passed Assistant Surgeon.*—To proceed to Buffalo, New York, and assume charge of the Service, January 3, 1889. Placed on waiting orders, January 12, 1889.

CARRINGTON, P. M., *Passed Assistant Surgeon.*—Granted leave of absence for thirty days, January 22, 1889.

WILLIAMS, L. L., *Passed Assistant Surgeon.*—Granted leave of absence for fifteen days, December 26, 1888.

PETTUS, W. J., *Assistant Surgeon.*—Ordered to examination for promotion, January 15, 1889.

MAGRUDER, G. M., *Assistant Surgeon.*—To proceed to Louisville, Kentucky, for temporary duty, January 22, 1889.

KINYOUN, J. J., *Assistant Surgeon.*—To proceed to Baltimore, Maryland, for temporary duty, December 29, 1888.

CONDICT, A. W. *Assistant Surgeon.*—Granted leave of absence for thirty days, January 25, 1889.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

THE PRESENT NEEDS OF SCIENTIFIC MEDICINE IN NEW YORK CITY.

The Inaugural Address of the President of the New York Academy of Medicine, delivered February 7, 1889.

BY ALFRED L. LOOMIS, M.D., LL.D.

FELLOWS OF THE ACADEMY: As I review the good work that has been done in the Academy during the past four years, under the guiding hand of Dr. Jacobi, I am impressed with the fact that he has inspired all its departments of scientific work with his own indomitable energy and broad culture. He has laid the foundations of a far more comprehensive structure than existed before. He has striven to make this Academy the centre of scientific medicine in this city—I might say, in this country. His labors have been unremitting, disinterested, and self-sacrificing, and he leaves the presidential chair with the highest esteem and gratitude of all its Fellows. How successfully the work which he has so ably begun was continued, must be told by those who years hence shall write our history. It is our hope and purpose that the "well done," with which history has already sealed the record of the past, may not be denied to the future.

I desire this evening to speak to you of "The Present Needs of Scientific Medicine in this City," and through you to the noble and broad-minded men and women whose hands and hearts are in every enterprise that tends to make our city the centre of material power, art, science, literature, and human charity.

It were perhaps more fitting on such an occasion as this, to indulge in mutual congratulations, rather than in criticisms; to recall battles won, storms that are past, and to speak of the brightening skies that overarch our present successes, but to those who battle for science the time for congratulations comes only when there are no new problems to be solved, no more wrongs to be righted, no faults that may be corrected, no needs that may be supplied, no new fields that may be explored, where faithful workers may perform greater achievements than have been reached in the past—surely no one who reads with intelligent insight the lessons of the past quarter of a century, and who realizes the necessities of scientific workers in every department of human knowledge, can fail to be impressed with the conviction that a higher and broader culture is needed in those who are entering these fields of labor, and in no one is this more apparent than in that of medicine. That there have been great advances in this respect during the past twenty years, few will question, but that the standard is still far below what it should be, is equally apparent.

The remedy for this is somewhat difficult to reach; certainly the entrance examinations to our colleges which have been proposed do not solve the problem. It seems almost ridiculous that a few questions in mathematics, the elements of physics, and the rudiments of language, less difficult and less comprehensive even than those required for entrance into our academic colleges, can be a satisfactory criterion of a candidate's fitness to commence the study of medicine. It is to be remembered "that a quarter of a century has wholly changed the relations of human knowledge," and that the natural sciences have become the chief factors in our modern civilization. Medicine, which once relied upon authority and tradition, is now rapidly seeking for its basis the natural sciences; medical students, of all others, should have a special education in these sciences; so long as a special training is not required as the important part of the preparation for entering upon the study of medicine, so long will the instruction in our medical colleges be incomplete and unsatisfactory. Defects in early training cannot be made good by excellence of professional teaching; mental equipoise, keenness of perception, analytical acumen, and intellectual power of differentiation between fact and fancy cannot be developed after the mind has become dwarfed during its years of plastic growth. To make cultured physicians, our colleges must be furnished with cultured men.

The remedy then lies more in the hands of the profession than in the colleges; when the profession shall realize their responsibility in this matter, and shall refuse to send to medical colleges, or advise to enter upon the study of medicine men devoid of natural talents, mental discipline, and intellectual power, then will the colleges be furnished with material capable of receiving the instruction which they have to give. In England, and on the continent, the higher general culture of the profession has so influenced the mass of medical men, that no uneducated man thinks of entering upon the study of medicine.

This is the first demand which medical science makes of us, that our "*esprit du corps*" be more sensitive, that our sense of personal responsibility be more keen, and with a courage born of conviction, and strengthened by the nobility of our calling, we hesitate not to say when occasion permits, "You are not fitted to be a physician, choose some other path of life." When we stand ready as a body to take this position, then, and not till then, will it be possible for our colleges to do that high grade of scientific work which is justly demanded of them. For, while we are justly proud, and have ample reason to congratulate ourselves on the many advancements that have been made both in graduate and post-graduate instruction in our city during the past twenty years, and while we are fully abreast, if not in advance, of our sister cities in this matter, we are still far from meeting the demand of scientific medicine; to answer fully its demands, the teaching bodies in our colleges must be placed on a higher plane, they must be separated from the financial interests of the colleges, vacancies in the

corps of instructors must be filled by fair competition, thus stimulating the younger members of the profession, who desire to make teaching their lifework, to prepare themselves by study and training to fill vacancies in our faculties as they shall occur. The curricula of our colleges must be so extended and subdivided that not only will a larger number of instructors be needed, and longer sessions required, but what is of far greater importance, that those who teach may by personal and familiar contact gain such intimate knowledge of each student, and firm control of his mental processes as will enable them to become teachers in the good old Anglo-Saxon sense—to be educators and not simply instructors pouring out their daily dole of wisdom into unreceptive ears.

All the facilities for laboratory work, original research, pathological study, clinical observation, and bedside instruction must be systematized, and largely increased. In fact, our medical colleges must be turned into workshops of scientific medicine, with skilled master workmen in every department, to guide, to lead, and, if necessary, to goad the young apprentice through his daily round of labor, until perfected, he shall go forth fully prepared to take an honorable place among the masters of the land. Not only should our colleges be thoroughly equipped with teachers and appliances for the training of undergraduate pupils, but they should be prepared to give well-trained men, after they have completed their graduate course facilities for study and experimentation in new fields of investigation.

Our laboratories should be so endowed that scholars of rare ability who are every year coming to our city for more knowledge may not only have places to work in, but means to work with.

Why is it then that in New York City, the centre of all honorable activity, where wealth groans for an outlet, any institution of human learning should be unable to do good work for the lack of money to do better. Why is it that men of wealth do not realize their great opportunities for wise liberality in this direction, liberalities which will not only shed lustre upon themselves and our city, but will mitigate human misery as certainly, and in many ways far more effectually than our hospitals and charities for the sick and suffering poor? My answer to these questions is, that the medical profession has not, as it should, directed the stream of accumulated wealth into this channel. The only appeal, until quite recently, has been for means to establish hospitals and charitable institutions, that to-day hospitals and dispensaries so far exceed the needs of the city that there is actually a premium on patients to fill their wards. Does any one doubt that if the profession would unitedly urge the great and pressing needs of our educational institutions upon generous minded men and women, they would respond as liberally as they have done for the erection and endowment of hospitals and dispensaries. If educated men and women by their words and writings would create a public opinion that a higher education in every department of human knowledge is the only lasting glory of a great city, that mental development is more to be desired than material prosperity, and that next to religion, education is the great corner-stone of our civilization, then would science break the bonds which now bind her, and be able to offer to knowledge-seekers who come to us from every portion of the civilized world, equal facilities for growth and development as are at present furnished by the centres of learning in the old world.

History tells us that the greatest glory of ancient cities, long since buried in ruins, was their universities and lyceums founded, reared, and fostered by the patronage and intelligent generosity of wealth and power. It is hardly possible to believe that this great city will much longer remain uncaring and unconscious of her greatest glory. The noble gifts which have been made during the past few years to educational institutions, and especially to medical colleges, inspire the hope that the stream of emotional benevolence for the sick and suffering is being turned into intellectual channels for higher educational needs and may we not believe that in the near future this city shall produce a class of medical men of broader culture who shall enter on their lifework from a higher plane, carrying with them to the couch of suffering better skill, greater devotion, and a more comprehensive realization of the nobility of the work to which they have given themselves?

In this connection there is need of establishment of scholarships, fellowships, and independent lectureships, which shall enable scholars of limited means to engage in scientific work. It is a part of history that as a rule the most faithful and efficient scientific medical work in this city has been done by men who, in their earlier professional life, had only such opportunities as they made for themselves, who were hampered, often almost to the verge of despair by their lack of means. While appreciating most fully the value of adversity in developing character, I believe it may be carried too far and that many stewards of idle millions will one day give an account for their failure to supply abundant means whereby brilliant men may be enabled to develop their full powers for the benefit of science and the common good.

There should also be created a public medical opinion which shall cause scientific attainments to become so much more honorable than mere professional success, which so often depends on social rather than mental powers, as to induce young men of wealth and intelligence to devote their lives to study and research. Such work might well be done in connection with our colleges or under the auspices of our medical societies. If there were twenty such places of work to-day, I am confident they would be quickly filled by enthusiastic and intelligent workers; and who can estimate the amount of good that would be done each year, and the great influence it would have in unveiling the obscurities which surround so many of the vital problems now pressing upon us for solution in almost every department of medicine?

Another need of scientific medicine in this city in common with that of our country—I may say the whole world—is a higher standard of medical literature. The American spirit of so-called enterprise presents no more deplorable manifestation than in the development of our medical literature. Before entering upon its criticism, however, let me say that no one appreciates more than I the value of the work of many faithful and conscientious laborers in the field—laborers whose writings are the expression of crystallized thought and experience, whose patience never fails, who know no self but only mankind, and who, with a supreme reverence for knowl-

edge and truth for its own sake, are devoting their lives to its development—it is because I recognize the power and greatness of such lives that I feel impelled to offer words of criticism on the redundancy of the medical writings of these latter days.

The *first* fault which I would name is vain repetition, "such as the heathen uses," and a lack of original thought. Our medical journals are filled with articles that show haste in their preparation and a lack of careful consideration in their statements—positive opinions are given unsustained by reliable data or extended observations, theoretical conclusions are put forth as established facts and not as questions demanding experimental answers. It were almost a work of supererogation to demonstrate to this audience that our medical journals too often publish articles that contain not the faintest trace of an idea which is not familiar to every student of medicine. So called original articles, clinical lectures, reports of special methods of treatment, all repeat the well-known facts that are found in every "Student's Compend," until we despair of finding the little gold among so much dross. To what shall we look for the cause of this?

First. A mistaken idea among the younger members of the profession. An idea for which many of us whose heads are silvering are in part to blame. The eager, ambitious young man, fresh from the hospital, filled with his own knowledge and exuberant life, imagines that the road to fame and wealth lies through the columns of the medical press, and that all who have once seen his name at the head of an article, remember it as though it were the writing upon the wall, and will immediately seek his services in consultation. Too often his ideal is given a halo by some older man who says write something for the journals, write often and let the profession know you. Let us confess this in garments of penitence, and in a more loyal spirit let us seek to inspire the younger members of the profession with higher ideals which shall foster in them the spirit of personal achievement, shall develop a pride in quality—not quantity—of mental products and that praiseworthy modesty which is content to learn until it is competent to teach.

The story or legend of that German savant who, after a life devoted to the five cases of the Greek noun, mourned upon his deathbed that he had not confined himself to the dative case alone, comes to us like a fairy tale or the record of an insane asylum. Yet let me tell you within that story, be it fact or fancy, lies the secret of noble achievement, of human progress, the essence of expanding, perfecting life of scientific work. It shows the soul capable of comprehending the infinite possibilities of science, and the self-forgetting ambition which can devote itself to the accomplishment of one thing worthily, whose sufficient reward is in the consciousness of having done faithful work.

When medical writings shall be filled with this spirit a year of the journal medical literature of the French, German, and English speaking people can no longer be condensed into five small octavo volumes.

I mention as the *second* cause of medical redundancy the speculative interests of medical publishers, financial necessities of unsuccessful physicians, and conceit of self-appointed authorities—each of these offers excuse for the establishment of a new medical journal and another waif is born to feed on patent foods and peptonic mixtures. The doors are thrown wide open and all aspiring young authors invited to enter, without cost, where fame is found at every turn.

Gentlemen, I appeal to you, are these the hands by which our noble science shall be upheld: are these the spirits to suffer and endeavor to work for a lifetime, if need be, that one new truth may be added to our store? They bring but broken stones and rotten beams which are not worthy a place in our temple of science, whose walls bear polished tablets to the memory of men who labored for truth not titles, for science not self, for mankind not money, for love not lucre.

As one enters upon an analysis of these requirements of higher medical culture and the demands of scientific medicine, he soon finds the essential element of each crystallizing into a single form about a single point, and realizes that the fundamental defect, the one first cause of the established fact that medical science has failed to keep pace with her sister sciences in this country, is a lack of high ideals among the mass of the profession—too often also among those who are justly its leaders.

As artisans we yield the palm to none—when science passes into art we seize every weapon it offers and wield them against the common adversary with such fearless force and skill as to cause even the forgers of these arms to confess our greater skill. But in the fields of pure science we still sit at the feet of the old world and in our secret heart at least confess we are as yet hardly competent to be even critics of its teachings. As a body we have yet to learn what scientific work means. That practical spirit, that Yankee ingenuity, born of adversity and developed by opposition, which has made us the foremost nation on the globe in all that tends toward material prosperity, and our growth, like the unfolding of a century plant, are the very elements that check—nay, forbid the growth of pure science. Every other science but ours tends directly toward the production of material results, toward the production of wealth. It is America that has seized Jove's thunderbolts and bounded them in the service of mankind; has made them meek and patient servants that do our bidding as does the muzzled ox, because the harnessed lightnings draw out the golden shekels. But he who seeks to bind in scientific laws the lightning of the mind or trace the labyrinth that lies twixt cortex and medulla, must never hope to see the gleam of gold; he feeds alone upon the thought that generations yet unborn will one day know the worth of all his patient work and will rise up to call him blessed.

It is not to be wondered at that the medical profession has been borne along with the multitude and has been given over to the search for patients and fees rather than bacteria and ptomaines. But it seems to me that the time has come when not the few (and all honor to these few who have been the advance guard) but the many should be given higher ideals; should be lifted to that higher plane where intellectual work is valued for what it produces new. No man surpasses his ideal, and before we excel in pure science our ideal must be one of intellectual power and not of material prosperity. But such ideals are not of individual creation like cathedral towers to be raised above contamination of earthly things into the clearer upper air, they must be the product of many hands and many minds, of united and concerted action. This seems to me the mission of our Academy, to be both the artist to conceive and form, and the guardian to preserve and sustain an ideal medical spirit of the

profession of this city and our country. No great conflict is ever waged successfully without one controlling mind: we have in this city many strong minds, but they are like an army of undrilled recruits, much of their work is rendered useless because unconcerted; often it is simply repetition which might have been avoided, and the general result is weakened in authority and lessened in value, because often incomplete and defective.

Medical men need a "clearing house," as much as do the banks; they need an exchange where each may bring the results of his work, and learn what his fellow-worker may have done in way of support or opposition, and most of all we need a controlling spirit, a head to plan lines of attack, to bring together the scattered forces for their own and the general good. It is my ambition to see the Academy occupy this position, standing as the centre about which all the workers of our city may gather, giving them in return loftier ideals, inspiring in them stronger ambition to be truly scientific men, while it not only encourages, assists, and stimulates them to better work, but also rewards every praiseworthy achievement.

In order that our Academy may thus become the centre of the scientific activities of the entire profession it must have a suitable home, a building that shall furnish accommodations for a large and well-selected library, with reading rooms and commodious meeting rooms for all the medical societies of the city. Such a building the Academy is now struggling to establish. Our organization is no longer an experiment, it has passed successfully through the perils and contentions of its infancy, childhood, and youth, and is now entering its full manhood. The spirit of devotion to a high scientific purpose which actuated its founders and which has always been one of its characteristics, has caused it from year to year to grow in professional esteem and public confidence until it may be truly said that it is the strongest power in this city for the advancement of scientific medicine. It has outgrown its building accommodations, its library can no longer find shelf-room and is constantly exposed to destruction, the building not being fire-proof. Its Sections crowd upon each other to such a degree that their work is crippled, it is unable to do the good work it might do on account of its limited space. The need of a new Academy building with a fire-proof section for our library is an urgent one, and if we shrink from our responsibilities in this matter, we shall prove false to the legacy received from those who gave so much of labor and sacrifice to bring it to its present growth and usefulness. As we recall the many distinguished men with whose lives it is interwoven, and who did so much to make it a centre of medical thought, are we not stimulated to greater endeavors, to greater sacrifice, to an energy akin to enthusiasm which never rests until it has realized the great thoughts and possibilities which gave it birth?

What has already been accomplished gives assurance of ultimate success; never before have its Fellows been so united in opinion as to the immediate necessity of a new building. The Academy funds, with the pledges of money which have already been received, leave little doubt that before another twelve-month it will have a new building in every way adapted to its scientific work. To the accomplishment of this, let each Fellow give himself heartily, not only by contributing himself, but by interesting his friends and gaining donations from them, for, as has often been stated, each citizen is personally interested in everything that shall advance medical science.

If the profession in this city can have free access to a large and well-selected medical library, with a scientific centre where they can contribute new observations, new facts, and new methods of treatment, subject to the criticism and judgment of their peers, and where each one shall criticise in a scientific spirit the offerings of others, the public will receive in their medical attendants greater skill, more careful and intelligent observation, and as the medical profession as a body shall rise to a higher plane of scientific worth, the sick will turn less frequently to empirics for relief in their hours of suffering and in their struggles with disease. The sanitary safety of our great city will no longer be committed to unprofessional and unscientific hands, but will seek the protection of a broader spirited and more enlightened profession, who, by wise councils and more practical methods, shall protect it from the ravages of those diseases which it is being demonstrated each year may be limited, if not altogether prevented, by the new and more advanced methods which are being formulated by a broader and more perfect sanitary science.

It does not seem possible that men of wealth, whether selfish or broad-spirited, with such and kindred thoughts before them, will long hesitate to furnish the required means not only to build a new Academy building, but for so increasing its library that it shall become the central attraction for scientific workers in our city and the whole country.

But, gentlemen, I would not speak only of the material interests of the Academy, of its building and library, I would congratulate you on the broader spirit which is being developed in its membership; we are each year becoming more tolerant toward the opinions of others. The links which bind together junior and senior members of the profession are being forged with greater strength. The jealousies and intolerance of cliques are fast giving place to liberality and good fellowship. The questions now asked concerning a Fellow are not of his birth or of his school, but "has he done good work, and is he likely to do more?" We rejoice in no medical politics, or medical ethics; a scientific atmosphere is pervading everything that is being done. Men, who heretofore have stood aloof, and who have done their work in special societies, are coming into its Sections and making them effective. This centralization should go on until in the Academy would be found all the best thought and the best work of the entire profession. Let it become the fountain from which shall flow the purest streams in every department of medical science, a place where the young and old, the savants and the young enthusiast shall cross swords in that spirit of deference which one scientific worker is always willing to accord to his fellow.

Treatment of Erysipelas.—DR. NOLTE (*Allgem. med. Centr. Ztg.*, No. 100, 1888) has in the treatment of this affection for years used mucilage of gum arabic with carbolic acid. The affected parts are painted daily with mucilage containing from a three to five per cent. carbolic acid solution, and allowed to dry.—*Therapeutische Monatshefte*, Jan. 1889.

CLINIC ON NERVOUS DISEASES.

Held at La Salpêtrière (Paris).

By PROF. CHARCOT.

(Specially reported for THE MEDICAL NEWS.)

DIAGNOSIS OF CAPSULAR HEMIANÆSTHESIA AND HYSTERICAL HEMIANÆSTHESIA.

THE case of this woman, which I bring before you to-day, may appear a very common one, yet it is a very interesting one, as there is a difficult question to find out. This woman's age is forty-seven, her father died in two days from cerebral apoplexy; this is all her family history. In regard to her personal history, she has been quite free from all sorts of diseases until two years ago, when she was attacked by the disease which has left her in her present state.

One evening in June, 1888, going to bed, she felt her head to be very heavy; the following morning she was found in an unconscious state, which lasted, it appears, about fourteen days. When she then came to herself, she was completely paralyzed on the right side, the paralysis affecting at the same time the inferior portion of the facial nerve, the upper and lower extremities; traces of this paralysis still persist to-day. She came to herself, according to her statement, at the end of fourteen days; but she does not remember, for after her return to consciousness she remained for several weeks more or less completely amnesic, whether her inferior extremity began to move first, or whether, on the contrary, it was the upper extremity, which would be contrary to what we usually observe; nor can she say exactly at what time she began to walk.

For the past year she has remained in the state we find her in to-day—that is, a hemiplegia affecting the right face, upper and lower extremities, with the particularity that the facial paralysis has persisted longer than usual, for ordinarily it disappears with time. I shall even add that the facial paralysis has remained much more accentuated than the paralysis of the extremities, which is an anomaly in a case of capsular hemiplegia.

You probably will say, "Why, this is a simple case of capsular hemiplegia, with certain particularities of a secondary order." I think it is a case of capsular hemiplegia, but let me recall to your memory the fact that the internal capsule can be involved in its anterior portion, in front of the genu, or in its posterior portion. If you find a more pronounced hemiplegia of the extremities, it is because, in all probability, the posterior portion of the internal capsule is involved. When you have a case in which facial paralysis persists, and this is very rare, it is when the anterior portion of the capsule has been involved. The portion of the pyramidal fasciculus which concerns the inferior facial (cortico-bulbar fasciculus) passes in the capsule in front of the genu, while the cortico-brachial and cortico-crural fasciculi of this same pyramidal fasciculus are placed behind the genu, the first one very near the genu, the second a little behind the preceding.

These facts have been demonstrated by both anatomical and clinical observations, as well as by the experiments on animals, and particularly on the monkey, by Pitres, Franck, Horsley, etc. In this manner you will comprehend that in capsular hemiplegia you might have sometimes a predominance of the facial paralysis, or, in other cases, the predominance of either the paralysis of the inferior or superior extremities. In most cases, this paralysis involves every one of these parts, and rarely, I repeat it, does facial paralysis persist very long in ordinary capsular hemiplegia, for in such cases experience has demonstrated that the posterior portion of the internal capsule alone has been destroyed by hemorrhage or softening, while the anterior portion, the one which concerns the movements of the face, has only been compressed, and not destroyed.

In this woman, I think, we have to deal with a capsular lesion, which consisted of a hemorrhagic effusion, to-day replaced by a cicatrix; but this lesion has involved at the same time, and very much so, the anterior portion of the internal capsule, as well as the posterior portion of the same. These last have been less severely injured, for, contrary to the rule, we find that the inferior extremity has been more profoundly affected than the superior. I explain this as follows: The hemorrhagic centre was longitudinal and curved, one of its extremities injuring the internal capsule in front of the genu, while the other extremity occupied the very posterior portion, but involving in part the cortico-brachial fibres which are between the two preceding tracts.

Let me say one word in regard to the paralysis of the inferior facial: it is not always easy to find it out when slightly pronounced. Is it necessary for me to recall to your memory the fact that the region of the inferior facial alone is involved in paralysis due to central clots, and that the non-involvement of the orbicularis palpebrarum establishes a contrast between peripheral facial paralysis, for this last is total, and affects at the same time the superior as well as the inferior facial?

The second patient I now place before you suffers from peripheral facial paralysis, or paralysis *a frigore;* as you may see, he cannot close his eye on the paralyzed side, while our right hemiplegic by capsular lesion can do so, and closes very well her right eye. We must not forget, however, that certain lesions of the protuberance can involve the facial when completely formed, and produce a total facial palsy, which would resemble the one produced by a lesion of the facial nerve at its exit from the Fallopian canal, but this is never seen in capsular lesions, or lesions of the cortex, paralysis of the inferior facial alone is found in such cases.

As I said a minute ago, facial paralysis, when not very apparent, is not always easy to define, and demands great care. Our female patient has a facial paralysis on the right side; on the same side she is hemiplegic, the right labial commissure is lowered, it is the paralyzed side; it is, on the contrary, elevated on the opposite side, where you find the naso-labial fold well marked; these are all usual symptoms. I shall add, also, that the lips on the paralyzed side are thin, and the mouth linear, while they are comparatively thick and the mouth slightly opened on the opposite side.

In such cases we are sure of our diagnosis; but sometimes the deviation of the mouth is much less pronounced, and the existence of facial paralysis can be doubted. In such cases, especially if the patient is of a certain age, consider the wrinkles. You can see on our patient how those on the lower and upper lips and chin are numerous, very accentuated on the non-paralyzed left side, while on the right side the skin is quite even.

Again, in the upper portion of the face you will find that the wrinkles are the same on either side. Again, if you tell your patient to show his tongue, according to the rule, when drawn out it is deviated on the paralyzed side—that is, in our case, on the right side, but here it is very slightly marked.

Let me call your attention to the fact that in cases of hemiplegia in which the tongue is deviated, the two halves are equal, one as broad as the other; the axis of the tongue remains linear, not curved toward the side where the mouth is deviated, as we shall see exists in certain cases which simulate hemiplegia of the inferior facial with deviation of the tongue, and in which we have no paralysis, but a spasmodic affection of which I shall speak to you in a few moments.

The father of this woman died from cerebral hemorrhage; she, herself, has had a cerebral hemorrhage—this is all very natural. You all know that cerebral hemorrhage is an hereditary disease. But you will say again to me: Where is that great interest you attach to your case? Well, here is the difficulty which makes out of this simple case a very interesting one for the clinician. It is that our patient is absolutely hemianæsthetic on the right side, as absolutely so as is the hemianæsthesia of hysteria; hemianæsthesia is so very pronounced in her case that you can introduce pins in any part of her paralyzed side without her feeling the least sensation; not only is she hemianæsthetic to the touch, but also to cold, pricking, and special sensations; half of the tongue does not taste bitter substances; the right nostril does not recognize odors as does the left; the right ear does not hear as well as the left. And, finally, the field of vision is narrowed on *both* sides, as is seen in hysterical patients, and, according to the rule, it is not hemiopic.

I have examined the fields of vision of hysterical patients thousands of times, and I desire to impress it on you once more, as the occasion presents itself, that I have always found a *double amblyopia more pronounced* on the *hemianæsthetized or unilateral* side, but *never* have I found *hemiopia*.

It is not usual to see hemianæsthesia, especially such a pronounced one as that we have before us, in a case of capsular hemiplegia. Briquet has said that when we meet with a very marked case of hemianæsthesia, we, in all probability, have to deal with an hysterical patient; in fact, a total hemianæsthesia is a very rare event in organic hemiplegia due to a hemorrhagic clot that involves more or less directly the internal capsule. There is a tendency amongst the young members of the profession to restore the opinion of Briquet. There was a time when, in the presence of a sensory or sensitive hemianæsthesia, the practitioner thought he had to deal with a case of lead-poisoning or alcoholism, for it was then thought that these two conditions could produce a hemianæsthesia resembling an hysterical hemianæsthesia. It has been demonstrated to-day, however, that when hemianæsthesia appears in an alcoholic or lead patient, it is due to the coexistence of hysteria in the same subject. This being admitted, we asked ourselves whether these hemianæsthesias were not due to a capsular lesion.

Turck's observations and mine have demonstrated to us, that certain capsular lesions can produce hemianæsthesia exactly similar to that presented by hysterical patients. Certain clinicians, however, question to-day their existence, and say that capsular hemianæsthesia does not exist. So that, according to the opinion of Briquet, every time one meets in a patient a more or less developed hemianæsthesia, this is almost certainly due to hysteria, and even reveals this condition. Well, I protest against such an assertion. Alcoholic and saturnine hemianæsthesias do no more exist. But capsular hemianæsthesia still persists,—it is very rarely completely developed; but such cases occur, and the one you have before you to-day is an example.

Let me mention to you the anatomical conditions found in cases in which sensory or sensitive hemianæsthesia is produced in combination with capsular hemiplegia, according to Turck's and my observations. It is when the lesion is situated at the extreme posterior region of the internal capsule, behind the region where the cortico-crural fibres of the pyramidal fasciculi pass—in fact, in the region which I have designated under the name of "carrefour sensitif" (sensitive cross-road). This I said twenty years ago; I have repeated it many times since, and I think myself authorized to repeat it to-day; and I shall add, that this capsular hemianæsthesia, when very accentuated, does not differ very essentially from hysterical hemianæsthesia, and particularly as regards the field of vision: it is not hemiopia that you will observe in such cases, but it is the crossed, unilateral, or double amblyopia, exactly as in cases of hysteria. Hence, leaving out of the question saturnine and alcoholic hemianæsthesias, which have no existence proper, although there are still alcoholic and saturnine anæsthesias, you see that, in a clinical point of view, we have to diagnosticate between capsular and hysterical hemianæsthesia.

To the old anatomico-clinical observations which have been presented, we can add to-day the cases which were presented some time ago, by Dr. Ferrier, before the Medical Society of London. These three cases, according to the author, resembled in every possible manner the symptoms observed in hysteria, yet at the autopsy he found lesions which occupied the "sensitive cross-road" at the posterior part of the internal capsule. Quite recently, M. Dejerine has presented before the Society of Anatomy of Paris, the history of a patient who had had a sudden hemiplegia developed at the same time a hemianæsthesia of special senses and sensation, as found in hysterics, made its appearance. At the post-mortem he found a hemorrhagic clot occupying the most posterior portion of the internal capsule. It is true, that this clot was of recent origin, while the cases related at the Medical Society of London, by Dr. Ferrier, were cases in which the lesion was an old one. If the hemianæsthesia of special senses and sensations is not encountered more often, it is because the hemorrhagic clots in capsular hemiplegia very rarely reach the "sensitive cross-road."

What demonstrates that our patient is not hysterical, is the fact that on the same side where there are a hemianæsthesia and hemiplegia there is also a palsy of the inferior facial nerve; and I am ready to maintain to-day, as I have done on former occasions, that hysterical hemiplegia involves exclusively the extremities, and does not, as is often the case in organic hemiplegia, involve the region supplied by the inferior facial. In this opinion I am sustained by the experience of Todd, De Hasse, Weir Mitchell, and others.

Affirming a certain fact brings about contradiction. If

you affirm that in hysterical hemiplegia there is no involvement of the inferior facial nerve, you will find a certain number of observations come up, demonstrating that the inferior facial can be involved in hysterical hemiplegia. Let us consider the matter more carefully. Facial palsy, due to capsular hemiplegia, with deviation of the tongue to the paralyzed side, can be imitated, in hysteria, and renders the diagnosis very troublesome, by an affection located in the region of the inferior facial, and producing also a deviation of the tongue and mouth, which affection is *not a palsy*, but a spasmodic affection. I have called attention to this pseudo-facial palsy in one of my clinics, delivered in the early part of 1887, and have named it

UNILATERAL GLOSSO-LABIAL SPASM OF HYSTERICS,

and in such hysterical patients it is not a palsy we have to deal with, but a spasm of the muscles and tongue supplied by the inferior facial.

I now place before you and beside our hemianæsthetic and hemiplegic patient with involvement of the inferior facial, a man whose case we will study in comparison with the former. This patient, although a man, is a very well developed hysteric—he is a characteristic type of major hysteria. His mother died insane, he himself has been very unlucky in his life—has had all sorts of troubles; he was one of our revolutionary soldiers during the Commune, was captured and sent to jail. Since then he has been always in a poor state of health, and whenever he requested admittance into a hospital for treatment he was rejected as a malingerer. It is true, he often contradicts himself in his statements and sometimes lies, but we must not overlook the fact of temporary amnesia, which is a mental state often encountered in hysteria of adult man; it is the physician's duty to make out what is true in his statements from what is false, and we must not reject such a man as a malingerer before his case is thoroughly studied. But he presents a number of symptoms which cannot be simulated, such as pharyngeal anæsthesia, shortening of the field of vision—and all the series of accidents which would be very difficult, even for an expert, to place in regular order.

The more male hysteria becomes known, the greater tendency have we to examine more carefully patients that present themselves to us, who would be often sent away as malingerers. Malingerers have a great tendency to exaggerate to an extreme degree the symptoms of the disease, whether it be insanity or hysteria, and it is always by studying carefully these exaggerated symptoms that we are able to make out the simulation.

Coming back to our male patient, I have had the opportunity, in past years, to be present at several of his hysterical attacks, which, I repeat, were classical. He suffers at present from a hemianæsthesia of the left side, a shortening of the field of vision, and hemiparesis on the same side. The motor hemiplegia has been more pronounced than it now is; this man who presents the above symptoms has, in addition, a hemiparesis of the left inferior facial. When he protrudes his tongue, it is carried to a marked degree to the left side—that is, on the paralyzed side, as is found in organic hemiplegia.

You certainly will say to me, why, a paralysis of the inferior facial in an hysterical patient—that contradicts all that you have just said. Examine the patient more carefully; when his tongue is protruded it is deviated to the left side, but notice at the same time that the lingual axis forms a very accentuated curve, the concavity of which is turned toward the left side so that the tongue does not remain straight as in paralysis, but forms a curve, a hook; the left half of the tongue also appears thicker and less broad than the right side; while in cases of paralysis the two halves of the tongue are equally broad; these facts would be sufficient to indicate that we have not to deal with a paralysis, but with a spasm, or, more correctly, a hemispasm.

This fact is confirmed when you examine the muscles of the inferior facial region; if you ask the patient to contract the muscles, the wrinkles are then more accentuated on the left side, on the chin, upper and lower lips, or the cheeks, much more so than on the right side; the contrary would take place had we before us a paralysis instead of a hemispasm.

I say again that the writers who have mentioned the existence of a paralysis of the inferior facial nerve in hysterical hemiplegia, have not sufficiently studied those glosso-labial spasms frequently found in hysterical hemiplegia and which have not been found, as far as I know, in capsular or organic hemiplegia. Lately, again, a Dutch author has recorded a case of hysteria with hemiplegia and involvement of the inferior facial. Well, I think in this case, according to the details given, that this patient, who was suspected to suffer from facial paralysis, was quite unable to protrude his tongue out of his mouth; this is not seen in simple organic hemiplegia and I would think it to be a case of hemispasm. You will say to me: Why do you not admit that in hysterical hemiplegia, which resembles so much organic hemiplegia, there should not be a palsy of the inferior facial nerve? As long as one cannot demonstrate to me that these so-called hysterical facial palsies are not hemispasms, I shall stand by my opinion until the moment when facial palsy, which I do not believe to exist in hysteria, shall become correctly demonstrated to me. From what I have just said, you are enabled to see that a marked hemiplegia of the inferior facial nerve can aid you to diagnosticate an organic or capsular hemiplegia.

What can be the physiological reason which seems to separate so widely hysterical from organic hemiplegia? I have shown you, in former years, that in hysterical patients who can be hypnotized it is easy for you to develop in them, by suggestion, all forms of hysterical paralysis, yet you cannot produce artificially a hemiplegia of the inferior facial, while, on the contrary, it is easy for you to obtain a glosso-labial spasm, exactly similar to the one we observe in our patients. The glosso-labial hemispasm which you see in the man before you, is sufficiently accentuated to be recognized, yet it is not a perfect example of the condition, but the man I now bring before you will help me to fix in your mind the characters of these hemispasms.

This poor man became hysterical two years ago, as a result of fright; he came near being run over by a large cart, and since then he has had a glosso-labial hemispasm of the left side, which we first took for a paralysis of the inferior facial. A more careful study of his case, however, showed plainly the nature of the disease. The tongue is directed toward the left side, but is in such a state of contraction and stiff, that the patient cannot draw it out of his mouth; it forms a very curved hook,

the concavity of which looks backward and to the left; at the same time the face is deviated; but the labial commissure being drawn upward and to the left, and the mouth on that side being slightly opened, it is easy to recognize the spasm, for the upper lip of the same, or left, side is almost continuously agitated by small convulsive tremblings.

Let me add, that the glosso-labial hemispasm can exist alone, without being combined with hemiplegia, such as is exemplified by the patient I now present before you.

HYSTERO-TRAUMATIC PARALYSIS.

You know that I maintain that hystero-traumatic paralysis possesses sufficiently marked characters that allow it to be recognized in the majority of cases.

Here we present to you a young patient who suffers from muscular atrophy, non-spinal amyotrophy, which has been named by Duchenne de Boulogne hereditary muscular atrophy; in addition, our young lady is a classical hysterical patient, and has a hemianæsthesia of the right side. I showed you, a few weeks ago, the case of a woman who, after having struck her child in the face, felt her hand hanging: that was a case of hystero-traumatic epilepsy.

Our present patient, a few days ago, while awaiting her turn to be electrified, in the adjoining room, where the electrization is going on, placed her hand unconsciously on the strap which communicated its movement to a static electric apparatus, and the left hand was slightly pinched between the strap and the motor wheel. As soon as this was done, the patient, very much frightened, felt in her left hand and forearm a certain numbness, and four or five minutes later *only* did the paralysis of the fingers and wrist present itself. It was at this moment absolutely impossible for her to move her fingers and wrist, which fell without any trace of contraction. Absolute cutaneous anæsthesia extending as far as the upper portion of the forearm, and limited by a line perpendicular to the axis of the forearm, assuming the form of a long glove, and deep anæsthesia of all the parts were found to exist.

All this is very correct, but here is the interesting fact: on the right side, where the hemianæsthesia was total before the accident, insensibility has completely disappeared from the hand, wrist, and lower half of the forearm, sensibility has returned on this right side, in exactly the same region, which is the only part insensible on the left side. In this case we have a transfer from one side to homologous parts on the other side, such as is sometimes obtained by the applications of metallic plates or a magnet according to Burq's method. Hence, the transfer of sensation can be produced by a traumatism, exactly as if æsthesiogenous agents had been applied; this I had never observed before under such circumstances.

It will probably be very easy for us to obtain a cure in this case; you know that I believe that hysterical contractures or palsies must not be allowed, as far as possible, to remain very long; it is usually very easy to make them disappear when they are of recent occurrence, but it is not so easy when they have lasted for some time. Our patient can be hypnotized; she presents the three stages of major or great hypnotism; we shall probably obtain a cure of this affection during the somnambulistic stage, by suggestion, as we have done already in certain cases, although not so often as we would have desired it.

It is natural for us to infer that such a transfer of sensibility, as is observed in the preceding case, is not an anomaly, an exception, but we can find it in analogous circumstances. A few days ago the same occurred in an hystero-epileptic in my service, but I did not bring her before you, as she was, according to my view, cured as soon as the hystero-traumatic epilepsy made its appearance. Her history is as follows:

Young lady, aged eighteen, easily hypnotized, presents all the characters of major hysteria, with a hemianæsthesia on the left side. One Sunday, being angry, because the stove of the ward did not give off enough heat, she kicked it vigorously with her left foot, which was in a normal condition at the time. Immediately after she had kicked the stove, however, the left leg and foot became very heavy, accompanied by a sensation of numbness; and when the patient tried to put her slipper on, which had fallen off, she remarked that her foot was hanging and absolutely insensible. The same occurred in this patient as had taken place with the other, when she placed her hand on the motor strap, producing paralysis of the hand. The foot in this last case was also completely and deeply anæsthetized, with loss of muscular and articular sensation. In this case, a transfer of sensation had also taken place to the right foot and the inferior part of the leg, which had previously been in a state of hemianæsthesia, now presented a normal sensation; this girl was cured of her paralysis by hypnotic suggestion.

HYSTERO-EPILEPSY.

This patient I present to you now, was treated eight years ago by my excellent colleague, Dr. Labbé, for six months, for attacks of epilepsy. According to the patient's statement, he had an aura, a sensation of vertigo was the beginning of the attack, and he gradually lost consciousness. He does not remember whether he felt constriction of the neck, but he recollects that he heard, previous to his attack, a whistling in his ears. He has had as many as seven fits a day; some of them would last two or three hours and when he had a fit several men were necessary to keep him down—he rolled about, twisted himself in every possible manner, and broke everything that came within his reach: such are his statements. He has been cured since he left the hospital.

Well, gentlemen, according to the description given us by this man, I think I can state that we have not a case of epilepsy to deal with. When an epileptic has a fit he is more quiet, he falls suddenly in a corner somewhere, and he does not strike around him, as this man has done, and four men are not necessary to keep him down; moreover, the evolution of the disease, the great number of fits in a relatively short time, the existence of a special aura, and finally the absolute cure of the patient, all indicate hysteria—and major hysteria.

He has never had any fit in bed, but he now occasionally awakens with a sentiment of fear. Let us see if there are no remains of hysteria, no shortening of the field of vision, or anæsthesia. Asking him why he comes to consult us, since he has been cured of his fits, he tells us that when he wants to cross a large empty square, the larger the empty place is the more frightened he is; he is unable to move his legs, they are as if they were

cut—he says that they are like lead; in addition, he experiences an indescribable emotion. If I ask him whether he is able to get over his fear, and cross the place, he tells me he cannot do so, and he fears he would lose consciousness should he attempt it. When he desires to cross a bridge he has the same fear, but to accomplish this he follows a car, looking in its interior, and, says he, should he find that he was going to feel bad he would jump into the car, and cross the bridge in that manner, without knowing it. This state is called "agoraphobia," a special nervous state, which has been discovered by Professor Westphal, of Berlin.

When travelling on a railroad he is frightened, because he feels he is locked in; and whenever he is placed in a narrow space he feels uneasy. The other day when a train in which he was began to move he had the sensation of a vertical or perpendicular rapid descent and he quickly rushed out of the car at the risk of killing himself; but the annoyance of this sensation was so great that he was unable to control himself. This is a vertigo or hallucination of translation, which occurs in a very slight degree in certain persons; when at night, the train begins to move, we feel suddenly as if the train was going in the opposite direction, and sometimes as if we were going perpendicularly down. While crossing a bridge in a train, our patient has also thrown himself down on the floor of the wagon, not knowing that he was doing it. This belongs to the section of height vertigo. The same occurs when he finds himself in a very high house, and looks out the window: he has then a terrible fear, a great uneasiness.

This state of fear and vertigo has existed only since he has had his convulsive disease. This disease he attributes to a fright; three men rushed on him one night, which caused him a great fright, which was followed by tremor; but this I only consider as an occasional cause. He dreams, and he has sometimes thrown himself out of bed, dreaming that he was falling. He is unmarried. He tells us a very interesting fact of his family history—his uncle died insane after two attacks of insanity. Here we have the real cause of his trouble, heredity. This case is a very interesting one to study.

ORIGINAL ARTICLES.

SOME HELPS IN GYNECOLOGICAL PRACTICE.

By W. A. N. DORLAND, M.D.,
OF PHILADELPHIA.

The class of patients met with in the practice of gynecology is of such a varied character, and the pathological conditions, though somewhat limited in their number, are of such frequent occurrence, that in whatever locality the practitioner may settle, unless strictly confining himself to some specialty in his profession, he necessarily is called upon sooner or later to alleviate the sufferings of these unfortunates to whom seems to have been portioned more than their due allotment of the ills of humanity. Too frequently, when such emergencies arise, does he find that that special branch of his medical education has either been sadly neglected by his alma mater, or carelessly overlooked by himself, and that, no matter where the fault may lie, he is utterly unable to respond with any degree of intelligence to these demands upon his professional skill.

It is with the desire to be of some assistance to such that the writer has sought this opportunity of advancing the suggestions which follow, not laying any claim whatever to originality, but merely stating that as they have been, from time to time, presented to his notice, he has thoroughly tested them in both private and hospital practice, and found them to be valuable and reliable adjuncts in the treatment of the respective conditions.

They are as follows:

In the first place, it will be noticed that the great majority of these patients present a marked degree of *anæmia*, as evidenced by the blanched conjunctivæ and lips, and general pallor of the skin. This anæmia is accompanied by the varied symptoms of dyspepsia—eructations of gas, poor or variable appetite, sometimes complete anorexia, a bad taste in the mouth, and severe headache, generally frontal in character. In such, often a marked improvement is manifested in a short time from the judicious use of some tonic such as the citrate of quinine and iron in two or three grain doses three times daily, or the following:

℞.—Strych. sulph. . . . gr. ss.
Acid. phosph dil. . . . ℥ij.
Liq. pepsin. . . . . q.s. ad. ℨiv.—M.

S. A dessertspoonful three times daily before meals. Under such treatment not only will there be a general improvement of the health, but the local condition will often be decidedly benefited.

Our attention will next be called to the *condition of the bowels*. These will generally be found to be constipated. Professor Goodell has said that, were he asked, he would define woman as "a constipated animal," and he would be justified in so doing, many women having but one or two evacuations weekly or even less, while a digital examination per vagina reveals large fecal masses widely distending the bowels. It is important that this condition be remedied, and this may be accomplished by the daily use of a drachm of the compound licorice powder taken at bedtime, or by divided doses of calomel, as the one-sixth of a grain in a small amount of the sugar of milk every half-hour till a grain has been taken, this amount generally proving sufficient to produce a free discharge of the hardened feces. In still more chronic cases we may employ one of the following mixtures according to the urgency of the condition:

℞.—Ferri sulph. exsic. . . . gr. xv to ℥ss.
Magnes. sulph. . . . ℥ij.—M.

S. A teaspoonful in a wineglassful of water with a little lemon-juice before breakfast.

or,

℞.—Aloin . . . . . gr. iij.
Res. podophyl. }
Ext. bellad. } . . . āā gr. iss.
M. Ft. Pil. No. xii.

S. One to be taken at bedtime.

By the employment of one or the other of these remedies, together with proper attention to the diet, the bowels may be easily regulated.

In almost every instance, *leucorrhœa* is one of the most prominent symptoms complained of. This may be simply the viscid, white-of-egg discharge of cervical endometritis, or the purulent and, at times, blood-streaked discharge of corporeal endometritis; or it may be the copious, thin, bloody, and offensive discharge of carcinoma, or the thin and purulent discharge of vaginitis, specific or otherwise. Whatever the condition producing it, it can only be properly treated by treating the cause. Where, however, this is not immediately possible, much can be done toward reducing the amount of the flow, and thus contributing to the cleanliness and comfort of the patient, by the use of the hot water douche. The patient should be advised to procure a fountain syringe, and instructed to inject, night and morning, a gallon of water as hot as can be conveniently borne, thoroughly up the vagina, lying upon her back at the edge of the bed with her feet resting upon two chairs, and a basin placed between to catch the water. These injections should be followed by a quart of hot water containing some astringent mixture, such as the following:

℞.—Plumb. acetat. . . . . ʒj.
Acid. borici . . . . . ʒij.—M.

Of this a teaspoonful should be employed in the injections. Considerable amelioration follows such treatment.

Endometritis is an extremely common affection, almost every woman presenting herself to the physician for examination revealing this condition to a greater or lesser extent; nor is it to be wondered at that such is the case, when we consider the great variety of causes, both predisposing and exciting, to which that delicate organ, the womb, is exposed. As to what these causes are and their degrees of frequency, the reader is referred to the text-books on the subject. Attended, as endometritis is, not only with local but also with marked general manifestations destroying the mental equanimity as well as the physical health and rendering life a burden to the wretched sufferers, it is all important that prompt and vigorous, as well as judicious and careful, attention should be given toward improving the condition of the endometrium in these cases. Much can be done in this direction by the use of the stronger (Churchhill's) tincture of iodine, the formula of which is as follows:

℞.—Potas. iodid. . . . . gr. xc.
Iodi. . . . . ʒijss.
Alcoholis . . . q. s. ad ℥iv.—M.

Applications of this made two or three times weekly, not only to the cervix but also to the canal, have a beneficial effect upon the unhealthy membrane.

When there has been a laceration of the cervix and considerable erosion and rolling out of the lips have followed, the iodine may be substituted by pure carbolic acid, to stimulate the eroded surface and bring it into a more active and healthy condition. Or an impervious coating may be formed over the raw surface, thus protecting it from the irritating leucorrhœa, by applying twice weekly the following preparation:

℞.—Iodoform . . . . . ʒj.
Acid. tannici . . . . . ʒiij.
Collodion . . . . . ℥ij.—M.

The bearing-down pain, so often complained of in these and, in fact, in all uterine and ovarian cases, may be relieved by the use of the hot water bag placed over the small of the back, and retained there for a considerable portion of the day, renewing the water as the temperature falls.

In many cases of *retroversion*, where the use of pessaries is not advisable, and where radical operation will not be permitted, temporary relief may be afforded by placing the patient in the Sims' position, and after reducing the displacement as far as possible by the finger, inserting far up behind the cervix one or two cotton tampons well saturated with glycerine. These often have a very pleasing effect upon the backache, and render the patient quite comfortable for the time.

They are also very serviceable in cases of *chronic cellulitis*, where there is much deposit of exudation around the womb and in the broad ligament. The hygroscopic properties of the glycerine draw to it the watery portions of the blood, thus aiding greatly in breaking down the exudate and removing it. The tampons should be withdrawn, in all cases, in thirty-six hours, and their removal will be followed by a free watery discharge from the vagina.

When there is much *irritability of the bladder*, from whatever cause, as shown by frequent micturition and inability to hold the contents of the organ, a happy result may be obtained by the use of some diuretic such as the following:

℞.—Ammon. benzoat. . . . . ʒij.
Infus. buchu . . . . . ℥vj.—M.
S. A tablespoonful every four hours.

The free administration of this preparation will be followed by a marked reduction in the vesical irritation, much to the satisfaction and relief of the patient.

In patients suffering from *menorrhagia*, *metrorrhagia*, or from *continuous and excessive flow after*

abortion, a most happy result may be obtained by administering equal portions of the tincture of the chloride of iron and the fluid extract of ergot, in doses proportionate to the severity of the case, varying from ten to thirty drops of each every three or four hours. The bleeding is controlled very promptly and efficiently under the employment of this combination.

In cases of *ovaritis*, *salpingitis*, and *inflammation of the broad ligament*, accompanied with severe pain in the groin and elsewhere, as indicative of the presence of an acute inflammatory process, where operative measures may not be resorted to, much relief may be afforded by active counter-irritation. This may be accomplished by painting the cervix and the vault of the vagina with Churchhill's tincture, and applying over the painful spots in the groins the following preparation:

℞.—Olei tiglii . . . . . ʒj.
Tr. iodi . . . . . ʒij.
Ætheris . . . . . ʒv.—M.

This must be repeated until a thick crop of pustules is produced, the irritation thus made acting favorably in checking the pathological process within.

In severe cases of *follicular vulvitis* with all its distressing group of symptoms, a very prompt termination to the sufferings may be brought about by applying to the sores a solution of silver nitrate of the strength of thirty grains to the ounce. The pruritus is relieved almost immediately, and sloughs are formed, which, separating, leave healthy ulcers which quickly heal.

Silver nitrate also is very useful in cases of *hemorrhagic urethra* accompanied with pouting of the lips of the meatus and intense engorgement of the delicate membrane. When the silver fails to accomplish its purpose, carbolic acid will usually suffice, destroying the engorged capillaries and causing a contraction of the dilated orifice.

The above comprises, as has been said, a few observations which may prove of assistance to some. Such, at least, is the sincere wish of the writer.

1521 South Thirteenth Street.

A CASE OF DOUBLE FRACTURE OF THE SKULL.

By THOMAS H. MANLEY, M.D.,
visiting surgeon to the harlem hospital, new york.

I offer this case to my professional brethren because it well illustrates the difficulties which often attend the diagnosis and prognosis of cranial lesions, especially those of a traumatic character.

B. M., male, aged thirty-five, fairly nourished, of medium size, was brought into the Harlem Hospital by the ambulance, at 2 A.M. January 6th. He was found, lying in a helpless condition, in an area, about eight feet beneath the sidewalk, by a patrolman, who was directed toward him by his groans. The officer, supposing him intoxicated, tried to arouse him, but did not succeed. He, however, discovered that the man was bleeding, from the head, quite freely.

After entering the hospital in a profoundly comatose condition, he was placed on the operating-table, when it was found that he had a scalp-wound above the ear, to the left, from which the blood freely oozed. The wound was enlarged by a crucial incision, and the surface of the skull carefully examined for fracture, but none was found.

He lay unconscious for nearly forty-eight hours, when reason gradually returned. The marked dilatation of the pupils disappeared; he changed from side to side, asked for food and drink, and, indeed, seemed to show evidence of returning health. This interval of lucidity, however, was of short duration, as he soon commenced to complain of pain about the forehead, and became more or less somnolent. At this juncture ten ounces of blood were quickly taken from the cephalic vein, hoping that this measure might abort the threatening meningeal trouble. He was much relieved by the venesection, brightened up, and said the pain was relieved greatly. Within ten hours he again relapsed into a stupor from which he could only be aroused with difficulty.

By the sixth day his temperature went up to 105°, and he was constantly muttering in a dazed, dreamy state. He would take no food, and had involuntary discharges. On the seventh day, for the first time, we found the pupil on the left side much contracted, the opposite about normal.

It was now evident that there was pressure somewhere close to the origin of the trigeminus, and that the brain-substance was being compressed by either pus or blood. I eliminated the latter, because of the patient regaining his reason, there being no paralysis, and the period at which those serious symptoms supervened. On the other hand, with the sudden rise of temperature, which was 105° in the morning, and went up to 105½° in the evening, I was naturally inclined to suspect an abscess formation.

On the afternoon of the 13th ult., the seventh day after his admission, he was again placed on the operating-table, the head having been cleanly shaved and scrubbed. At this time he was quite weak, and it was thought that if the difficulty could be reached life might be prolonged, but, at the same time, we also saw that the shock of operation would tend to enfeeble him more.

A free incision was now made through the old wound, all the tissues drawn away from the original incision, and the pericranium elevated, or rather *scraped off the skull*, thereby bringing the bare, denuded bone-surface into view, when a fracture was discovered, of a quite small area, triangular in form, at the junction of the temporal, parietal, and frontal bones; it was but slightly depressed. Over this rent the trephine was placed, and a large button of bone removed in pieces.

We were very cautious, in going through the inner table, not to wound the dura mater; but we found this care unnecessary, as between the inner surface

of the cranium and its fibrous investment there was a space of more than half an inch filled with a firm, compact blood-clot. A second circle of bone was removed, to make room for operating within the cranium, and thoroughly displacing this large mass of coagulated blood.

The index-finger was passed in, and the clot, which was well organized, was broken up and displaced. The finger was carried in every direction, down even to the petrous portion of the temporal bone, and, with the aid of the irrigator, every portion of this foreign body removed. After the removal of this immense mass, the brain did not expand in the least, and a large, hollow space was left.

Antiseptics were rigidly applied throughout. Now, that this effusion and pressure were removed, we looked for some hopeful signs from our patient, but our efforts proved futile. He became chalky-white, and the extremities cold; in fact, he was suffering from shock, with alarming depression of the vital powers. I raised up the lid of the left eye, and found the pupil *still contracted*, notwithstanding what had been done.

Besides my colleague, Dr. John G. Truax, there were several other medical gentlemen present, who, with myself, supposed the patient would have rallied after what we presumed must be a successful operation.

Heat and the usual restoratives were most assiduously applied, but he gradually succumbed at 8 P.M., four hours after the operation of trephining.

The query now very properly was, What caused his death? Was it caused by delaying the operation too long? It will be remembered that I had the assurance of the house-staff that no evidence of fracture could be found when admitted; hence I assumed that it was probably a case of concussion, until graver symptoms supervened. After carefully studying the matter over myself, I decided that he probably died from loss of blood during the operation. I thought it possible that, in displacing the clot, we might have reopened the vessel from which the original leak sprung; hence I made up my mind, if I ever should cut down on a similar formation, I would be more chary about removing it all at once.

We were fortunate in getting permission to open the head after death, when, to our amazement, we found a large fracture at the base of the skull, entirely independent of the fracture described, extending from the foramen magnum up through the occipital well into the perietal bone. No hemorrhage was found in the course of this fracture. The hemorrhage contributing toward the removed clot was found to have come from the vessels of the diploë pushing away from the skull the dura mater, as it increased in volume, until it had torn up a section of this membrane nearly as large as the palm.

This man then had, along with the fracture anteriorly, a fracture of the *base*, without a single symptom of this mortal lesion, if we except coma. No hemorrhage from the ears, no suffusion of the loose, cellular tissues about the eyes, and not the slightest paralysis.

The singular course of this quite unique case I believe to be of sufficient interest to publish, as such are rarely met with. I have now treated one hundred and fifteen fractures of the skull in hospital, but the peculiarities and puzzling features of any similar to the one recorded I have never before met.

THE CURVILINEAR REFLECTION OF WEISS AS A PRODROMAL SIGN OF MYOPIA.

BY B. ALEX. RANDALL, A.M., M.D.,
OPHTHALMIC AND AURAL SURGEON TO THE EPISCOPAL AND CHILDREN'S HOSPITALS, PHILADELPHIA.

IN a paper read before the Heidelberg Ophthalmological Society, in September, 1885, Dr. L. Weiss discussed as "the earliest variation in the near-sighted or near-sighted-becoming eye," an appearance in the eye-ground to which he had called attention at the Baden-Baden meeting of the German Naturalists and Physicians in 1879. This appearance he described as a brilliant curvilinear reflection to the nasal side of the optic disk, and nearly concentric with it. Its length, breadth, and distance from the disk-margin may vary considerably, not only in different cases, but even in any given case with variations in the illumination. He differentiated it from the numerous flitting reflexes of the retina so marked at times in the eyes of children—the watered-silk retina of some English writers—by its form, its relative steadiness, and its relation to the inner margin of the nerve; but especially by its position decidedly in advance of the eye-ground. The more near-sighted the eye in a progressive case, the further out in the vitreous chamber would it generally appear, and the more widely to the nasal side of the disk. Examining the eyes of the pupils in a gymnasium and preparatory school in Manheim, with reference to the frequency of its occurrence, he found it in 20.6 per cent. of 446 hypermetropic, in 32.6 per cent. of 356 emmetropic, and in 69.4 per cent. of 292 myopic eyes—in 38 per cent. of the total 1074 eyes studied. It was, therefore, not at all confined to the myopic eye, although more frequently there seen; its importance lay in its marking the *distending* eyeball, whatever its refraction, and in furnishing a most valuable prodromal sign of myopia early enough to permit of combating the evil.

As to the causation of the appearance, Dr. Weiss claimed that it was due to the presence of fluid in front of the optic nerve entrance—fluid separating the vitreous from the retina over a limited area at the posterior pole of the eyeball—and that the curved boundary of this collection formed the surface from which the reflection proceeded. His investigations

of myopic eyes (*Mittheilungen aus d. Tübingen Augenklinik*, I. 3, p. 63) had shown such collections and a sharp bending of the optic nerve at its entrance—a condition likely to interfere with the natural outflow of the intraocular fluid, and to account for such a collection within at the posterior pole; and while regarding, with v. Hasner the traction upon the nerve-entrance exercised in convergence by a too short optic nerve as the prime cause of myopia, he held that the fluid thus detaching the vitreous was not only a symptom of the distention, but also, by its pressure, one of the factors in its production.

The pointing out of so important a prodromal sign of myopic distention by an investigator whose previous work had been so valuable, could not but challenge attention; and ever since Dr. Weiss's first note upon the subject, but especially since his later paper, which was published in full in Graefe's *Archives*, xxxi., 3, p. 239, the writer, like many others, doubtless, has been endeavoring to study the matter. The point was unquestionably a new one; and it seemed a little humiliating that in ophthalmoscopic work which he had flattered himself was careful, he had never taken cognizance of such an appearance. The total failure, however, to find it in hundreds of cases in which it was sought with scrupulous care had nearly changed his humiliation into utter scepticism; when a case came under observation, presenting so clearly the points of interest to which Weiss had called attention, that it has seemed proper to place it upon record, with some remarks upon a subject which has been little dealt with in English.

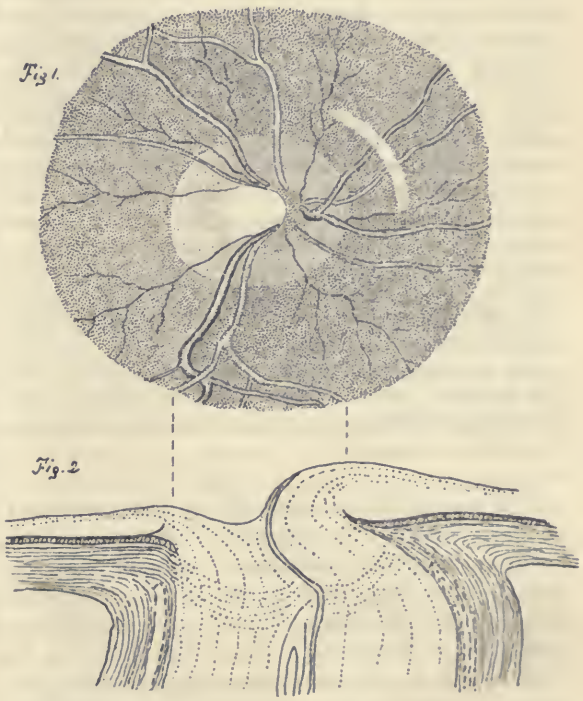
Sally L., aged eleven, came to the Eye Dispensary of the Episcopal Hospital on October 29, 1886. The brief and imperfect notes show that her myopic astigmation was measured under atropine, and her glass as given for constant wear was

O. D.—3. 5 sph.—2.25 cyl. ax. 150° $\frac{20}{LXXX}$

O. S.—1.5 sph. $\frac{20}{XL}$.

While the record fails to show full details as to the normal appearances of the eye-ground, the completeness of the paralysis of accommodation, or even that the full correction was ordered, it is safe to assume that the contrary would have been noted in accordance with the usual routine. She returned on March 2, 1888, complaining that her vision was no longer sharp through her glass; and examination showed a greatly lowered vision, especially on the right, due to an apparent progression in the myopia. Under full atropine mydriasis, the left eye showed unchanged refraction and vision; but the right eye now required —6 sph.—1.50 cyl. ax. 150°, and obtained a vision of $\frac{20}{LXIV}$. There was marked tendency to divergence of the right eye, which lessened materially under the use of the correcting-glass, but remained periodic, and gave rise to double vision. A tenotomy of the right externus was done after some weeks, there being full excursion of the eyes in all directions, with the result of greatly lessening the deviation; and several weeks after the operation diplopia had disappeared, the eyes could be maintained in parallelism, and the vision was better with both eyes than with the right eye covered. She did not return until recently, when requested to do so, having been comfortable; but examination now shows renewed deviation of the right eye and lowered vision, apparently due to still further increase of the myopia on the right side.

In March, 1888, her eye-ground presented the appearance shown in the cut (Fig. 1), and has



Randall

changed little, if at all, in the last nine months. The optic disk is horizontally oval, with a considerable central excavation, of which the nasal margin is abrupt and overhanging, while the temporal side shelves gradually. The disk margins are slightly veiled by retinal striation, but everywhere discernible, and show neither heaping nor notable absorption of pigment—although down and out there is slight broadening of the scleral ring and the disk is least clearly defined here. Most of the vessels pass through the substance of the nerve-head, as the central artery divides before coming into view; some of them come from beneath the overhanging margin of the excavation. The whole nerve-entrance presents some of that appearance of "drag" to which Thomson and others have called attention; and, in accordance with the usual findings in such cases, the ophthalmoscope shows a considerable difference of level on the two sides. The nasal margin

of the disk is between one and two dioptres more prominent than the temporal.

To the upper nasal side of the papilla, less than half a disk-diameter from the margin, is a strong crescentic or curvilinear reflection which nearly hides the vessels which pass beneath it. Variations of the illumination cause it to shift and alter slightly, but its character and position are quite as fairly fixed as those of the reflection from the *fovea centralis*. Like the latter and other retinal reflexes, it is best seen with a convex glass in addition to the correcting-glass, and almost disappears from view when the underlying retinal details are sharply focussed. Bright, shifting reflexes are visible elsewhere in the fundus, especially along the major vessels; but these are by no means so marked as they often are in the eyes of children, and have none of the constancy of the phenomenon in question. At the first glance into the eye the peculiarity and individuality of this crescentic reflection struck me, before any other details had been noted, and I remarked to my assistant that I had found something which I had vainly sought for years. Repeated careful examination affords no visible evidence of that "supra-traction of the choroid" of which Nagel and his pupils make much note; and while the oblique position of the disk is unmistakable, it is noteworthy that in spite of the foreshortening incident to this, and although there is no broad scleral ring or conus to its outer side, the disk still appears wider horizontally than vertically. The left eye shows an eye-ground similar in most respects; but the reflection, while present, is far less characteristic in form, and blends with the ordinary reflexes along the adjacent vessels.

The question of the causation of this appearance seems important. In view of the conspicuous character of the present condition, it is hard to believe that it could have been present at the examination eighteen months ago, and have been wholly overlooked, at a time when I was rather more on the lookout for it, having recently read Weiss's later paper. The study was at that time unsatisfactory in that only $\frac{20}{LXXX}$ of the normal vision was obtained; and it is quite certain, although neither the record nor my memory serves to prove it, that repeated ophthalmoscopic examinations were made in the endeavor to improve the correction, or to obtain an explanation of the defective vision. Probably, therefore, the curvilinear reflection has appeared since the eye has suffered the increase of some two dioptres in its myopia, and is dependent upon the anatomical changes incident to that lengthening by about one millimetre of the visual axis. Most careful study gives no faintest evidence of fluid in front of the optic nerve. Cases of detachment of the vitreous by exudation in front of the retina at the posterior pole have come to my notice, and were readily recognized and correctly interpreted before I had seen reference to them by others. I am, therefore, as little prepared to admit the presence of fluid here upon this one bit of assumed evidence, as I am to concede the opposing view of Stilling, that there is *always* fluid between the vitreous and the posterior pole, filling a lymph-space which normally exists there (area Martegiani). If there be normally *ante-mortem* a trumpet-shaped cavity in the vitreous body, with its expanded mouth over the optic nerve entrance, ophthalmoscopic evidence of it is wholly wanting—the rare persistence of a visible "Cloquet's canal" being the exception which proves the rule. On the other hand, a glance at the section of the optic entrance in the myopic eye offers an immediate and satisfactory explanation of the phenomenon in question.

In Fig. 2 we have a tracing of one of Weiss's sections of the nerve from a slightly myopic eye (*Mittheilungen aus d. Tübingen Augenklinik*, i., 3, Pl. i.), and in all respects, except the grade of myopia, it closely corresponds to the findings in the case before us. The "drag" of the nerve-head, so generally found in such cases, is very evident, and the distention of the papilla is marked; while the form of the excavation, the prominence of the nasal margin, and the relation of the vessels are well shown. The excessively bent nerve-fibres at the nasal margin form a marked prominence, the most convex portion of which lies a little outside of the nasal margin and forms a surface eminently fitted to give back the crescentic reflection of light with which we here have to do. Close scrutiny of the present case shows no discrepancy between phenomenon and explanation. The reflection, while most marked when out of focus, can still be seen when the summit of the prominence is sharply defined; and this explanation, once considered, seems wholly to supplant any other in the case before us.

While this paper has been awaiting completion, it has seemed wise to renew the search for other instances of the phenomenon, and a series of fifty cases has been studied with scrupulous care. The examination has been made always with the undilated pupil (although often repeated with the dilated pupil), since retinal reflexes, such as the halo around the macula, are always best seen before mydriasis, sometimes wholly disappearing upon dilatation. The individuals have all been young, generally under age; and not a few of them myopic and with distorted disks, where the appearance in question might be expected. Two elder sisters of our patient, presenting similar refraction and eye-grounds, were among those studied with a negative finding. Of the fifty cases, one girl of seventeen, with H. As. ($+0.50$ sph. $\supset +0.50$ cyl. ax. 50° and 130°) in each eye, showed the curvilinear reflection in its typical form, although there was no measurable prominence of the nasal margin. The common grayish absorbing pigment ring or band to the inner side of the disk,

which Nagel regards as evidence of "supra-traction of the choroid," was quite marked in both eyes. Four other cases presented in one eye a reflex more or less corresponding in form or position to the appearance under discussion, and were demonstrable to others as atypical instances of its occurrence. Four or five others showed shimmering reflexes up and in, too completely lacking any characteristic difference from the reflexes elsewhere visible to be counted as cases in point. Of one hundred eyes, therefore, six only could be said to have presented the curvilinear reflection of Weiss. One other myopic eye, not included in the series, presented a fairly characteristic instance; so I may say that four typical examples of the appearance, and four cases that might be regarded as atypical instances, have come to my notice in the years during which I have sought it.

Small as is the series cited, its negative showing, corroborated by several years of daily experience, convinces me that the "reflex bogen-streif" of Weiss is not present in any notable percentage of cases in this locality, and leads me to doubt the frequency of its occurrence in Germany. Such a statement seems fair, in spite of its recoiling effect—calling into question the skill of the ophthalmoscopist who simply *has not seen;* and comparison of notes with other observers who have seen some instances of the appearance in question, confirms the view as to the rarity of its occurrence.

The theory of Weiss as to its causation appears to be strained. Repeated examination of the phenomenon in the case above reported has wholly failed to furnish the faintest ophthalmoscopic evidence of a collection of fluid in front of the disk. Probably such a collection would become visible only on losing its transparency, as had happened in the cases of detachment of the vitreous which I have seen. Yet some indication ought to be discoverable, if we really have here a detachment of the vitreous. Weiss's claim that the reflecting surface is measurably in advance of the retina (+1 to 4 D.) is not borne out in my limited observation; and upon it rests most of his explanatory theory. In the cases which I have studied, the reflection could be most clearly seen when the retina was out of focus, but could be followed down until the retinal surface was focussed. In this it differed in no wise from the halo around the macula, the crescentic reflection from the *fovea centralis*, or the shimmering "shot-silk" reflexes along the vessels, unless in that it could be *more* clearly seen at the retinal level.

Although Weiss has based his views upon some very important observed facts, there is too much of unproven assumption in his explanation. He starts with the point that all infants are hypermetropic, that older children are less so, and that adults are still less, or have become emmetropic or myopic. Part of this increase in refraction he ascribes to physiological growth—change of curvatures, dimensions, and refractive indices; but part he thinks due to *distention.* In a paper presented at the recent Congress in Heidelberg (*Bericht VII. Internat. Ophth. Congress*, 1888, p. 513), I furnished evidence that this increase in refraction is certainly less than has been claimed, and that "the results must be set down as rather negative, except in wholly failing to support the theory of a physiological progress toward myopia." Cases of distention do occur, as every ophthalmologist of experience has witnessed; and extensive series have been recorded by Risley, Norris (*Trans. Amer. Ophth. Soc.*, 1884, 1885, and 1886), and others. In distending posteriorly, the vitreous chamber becomes enlarged; but it is an assumption quite in opposition to our scanty knowledge of the spongy, bibulous character of the vitreous body, to claim that it is incapable of enlarging to fill the increased area. Loss of vitreous in cataract operations would be of far more serious import were that body destitute of regenerative or expansive character. More extended observation and fuller proof are needed before we can accept the view that in all distending eyes, or in the majority of them, notable collections of fluid must form to occupy the enlarged vitreous chamber. The claim that 38 per cent. of the eyes of school children present a form of detachment of the vitreous will need much modification, or more thorough substantiation, before it will find many supporters.

In conclusion, I desire to ask a careful study of this interesting question, which may have in it much practical importance, although its premises seem as yet insufficient, by all those interested in ophthalmology. The phenomenon described by Weiss undoubtedly exists; and, while striking examples of it are rare and considerable difficulty will be met in recognizing it at first, after it has been once seen its peculiar character will be apparent. I think it not unlikely that I will observe it more frequently in the future than heretofore, and hope at a later time to discuss it more thoroughly.

MEDICAL PROGRESS.

Statistics of Operations on the Gall-bladder.—Dr. A. Depage, in the course of a paper upon "Surgical Intervention in Biliary Lithiasis" (*Journ. de Méd. Bruxelles*, 1888, No. 24), says that up to the present there have been 78 cholecystotomies performed. Of these operations, 6 were done according to the method of Spencer Wells, 72 with suture of the gall-bladder to the abdominal wall. Of the first-named series, 3 died from acute peritonitis, 1 cured case was followed by recurrence, and 2 cases were completely cured. Of the second series there were 11 deaths, 5 from hemorrhage and collapse, 2 from biliary retention, 2 from effusion of bile into the peritoneum, and 2 from undetermined cause; there were also 4 deaths from sec-

ondary complications. Amongst the "cures" are 24 cases of biliary fistula, some permanent. The number of cholecystectomies has been 22, with 2 deaths from obstruction of the bile-duct, and 1 after recovery from the operation from a cause independent of biliary lithiasis. Thus, in cholecystotomy with suture of the gall-bladder, and its return free into the abdominal cavity, a mortality of 50 per cent. resulted; in cholecystotomy with suture of the bladder to the parietes, 15.27 per cent.; and in cholecystectomy, 9.99 per cent.; and as the last-named figure comprises the two cases of permanent occlusion of the common bile-duct, the result, if they be excluded, is to enhance greatly the position of cholecystectomy as an operation to be preferred to cholecystotomy.—*Lancet*, Jan. 12, 1889.

A Case of Creolin Poisoning.—DR. CRAMER reports the following: a five year old boy, upon whom he had operated for an inguinal hernia, was ordered applications of gauze saturated with a two per cent. creolin solution, the same antiseptic solution having been used during the operation. Everything went on satisfactorily, no fever set in, the urine continued clear for three days after the operation; in fact, the general condition was excellent. On the evening of the third day, Dr Cramer was called to the patient's bedside to treat, what seemed to the parents, to be scarlet fever. He found the entire body including the face and hands, covered with an exanthem resembling scarlet fever; the little patient appeared extremely restless, complained of great thirst, and of an itching and burning of the skin; temperature was normal, pulse somewhat rapid and small. The urine had a strong carbolic acid odor, as well as the characteristic carbolic acid color.

Dr. Cramer immediately replaced the creolin applications by a three per cent. boric acid solution and administered internally large quantities of seltzer water in order to facilitate the elimination of the creolin through the kidneys. The exanthem lasted until the following morning when it disappeared; but the urine remained dark until the following evening. The boy made a complete recovery.—*Therap. Monatshefte.*

Action of Phenacetin and Sulphonal.—DR. ADOLPHUS OTT, of Prague, in a recent number of the *Prager med. Wochenschrift*, gives some further details as to the effect of phenacetin and sulphonal. With regard to phenacetin as an antipyretic, Professor Ott's experience agreed with that of other investigators. With respect to the drug as an antineuralgic, Professor Ott states that there was hardly any neuralgia, either reflex or peripheral in origin, which could not be influenced by phenacetin. It was only in diseases of the central nervous system, in affections of the brain and the spinal cord that the drug failed in most cases to produce any effect. The best results with phenacetin were obtained in hemicrania and occipital neuralgia. In pure neuralgia of the fifth nerve the effect was only temporary; in one case of severe sciatica, the medicament was useless. In Professor Ott's hands sulphonal proved to be a very good hypnotic. In most cases, tranquil and prolonged sleep supervened after the administration of from one to two grammes. Ott also relates the following interesting observations. On one occasion he had under his care a case of hypochondriasis with arthritic disposition and temporary arhythmia of the heart. The patient, who was accustomed to the injection of morphine, slept well after the administration of two grammes of sulphonal, and the arhythmia always ceased a few minutes after the administration. In another case, however—that of an hysterical girl, aged twenty-nine, who was also accustomed to morphine—no effect could be obtained even with a dose of three grammes. This last observation agreed with Oesterreicher's statement that sulphonal had no effect during abstinence from morphine. It also failed in one case of sciatic neuralgia. The drug was very well borne; no bad after-effects were observed except a sensation of weariness on awaking. In one case of severe chronic catarrh of the stomach combined with nervous irritability and sleeplessness, in which three grammes of sulphonal were given, vomiting and fainting fits occurred. —*British Med. Journal*, Jan. 12, 1889.

For Hysterical Vomiting.—DR. EWALD recommends for this affection the following prescription, of which from ten to fifteen drops are to be taken hourly:

℞.—Hydrochlorate of morphia	. .	3 grs.
Hydrochlorate of cocaine	. .	5 grs.
Tincture of belladonna	. .	75 minims.
Cherry-laurel water	. . .	℥vjss.

—*Revue de Thérapeutique*, Jan. 15, 1889.

A Sulphonal Exanthem.—DR. SCHOTTEN, of Cassel, reports the case of a delicate, nervous woman, forty-five years of age, suffering from chronic myelitis, who for one year had regularly taken chloral on retiring. On the night of August 29th, this patient was given thirty grains of sulphonal; it did not produce sleep, but rather a sense of extreme fatigue. The following evening thirty grains more were administered, with the same effects. On the third evening forty-five grains were administered. This was followed by a prolonged sleep, but on awaking the patient complained of a peculiar feeling of extreme fatigue, manifested by great inclination to sleep, hanging of the head, and difficult motion of the tongue; besides this she complained of headache, of bitter taste, and of loss of appetite. This condition lasted four days, after which time an exanthem made its appearance, beginning on the head and gradually extending over the entire body, resembling in form and color the eruption of measles. The body was hot; the skin had a burning sensation; the mucous membranes were not affected. With the appearance of the eruption, the symptoms of fatigue, etc., gradually disappeared. The exanthem lasted two days, after which it slowly disappeared, leaving traces which were yet noticeable on the fourteenth day.

A sister of this patient was similarly affected after taking antipyrin.—*Wiener med. Presse*, No. 52.

Poisoning by Hydrate of Amylene.—DR. DIETZ (*Deutsche med. Zeitg.*, 1888, No. 24) reports the following: A mixture containing hydrate of amylene was prepared for occasional administration to the patients of a clinic in Leipzig in order to procure sleep. Directions were given to shake the bottle before pouring out the dose. On one occasion the bottle was allowed to stand for a few moments after having been shaken, and then four separate doses for four patients were administered. Amylene hy-

drate being of light specific gravity floats on water, the result being that the dose under these conditions was greatly increased. The symptoms produced in all four of the patients who took the drug were those of acute poisoning by alcohol—prolonged sleep, paralysis of the extremities, abolition of tactile sensibility and of the reflexes, dilatation of the pupils with feeble reaction to light, superficial, irregular respiration, and small, slow pulse. Hypodermatic injections of camphor was the treatment adopted, all the four patients recovering.—*Medical Chronicle*, January, 1889.

Treatment of Eczema.—DR. VEIEL, of Cannstatt (*Med. Corr.-Blatt d. Württ. ärztl. Landesver*, August Heft), writes upon this subject as follows: When treating an eczema, distinction must be made between the acute and chronic form. In the acute form no internal treatment is required, while in the chronic form, arsenic internally, and proper remedial measures externally, are essential. When chlorosis is present, one should administer iron one hour before meals, and arsenic one hour after the same. Scrofulous eczema of children is best treated with cod-liver oil and an appropriate diet combined, if the itching is very annoying, with the internal administration of chloral and bromide of potassium.

In the acute variety, anything that might possibly irritate the skin must be avoided. Children who cannot very well do without their daily bath, should have some slimy substance added to the same. Soap in any form or shape must be avoided. To allay the burning and itching of an acute and dry eczema, Unna recommends the following:

℞.—Oxide of zinc } Gelatine }	. . . . .	āā ʒiv.
Glycerine	. . . . .	ʒviss.
Water	. . . . .	ʒiss.—M.

Heat for a few moments, and apply with a camel's-hair brush.

In moist eczema, the affected parts should be thoroughly washed once daily, then dried, and some flour or starch applied. In cases in which this proves of no avail, the author makes use of a pillow filled with powdered starch; the effect is a cooling one, but requires frequent changing. Where the itching is severe, and the starch alone does not give relief, the parts should be powdered with starch to which two per cent. of camphor has been added. Should this still not alleviate the irritation, the parts should be washed with the following:

℞.—Solution of acetate of aluminum	.	ʒijss.
Water	. . . . .	ʒiij.
Borax	. . . . .	55 grains.
Salicylic acid	. . . .	5 grains.
Water	. . . . .	ʒvss.
Glycerine	. . . . .	ʒj.—M.

In the wide-spreading and moist eczema, salves and pastes are of service. Thus, if the eruption has become dry and squamous, a five per cent. tannin salve should be applied. In chronic eczemas the crusts and scales should be detached by bathing, or by applying soft-soap or oil; the addition of one to two per cent. of ichthyol to any of the foregoing will greatly assist their action. If, in spite of this, the scaling should still continue, Lassar's paste, or tar in alcohol, should be applied:

℞.—Liquid tar	. . . . .	1 part.
Alcohol	. . . . .	3 parts.

This formula is not to be applied to any hairy portion of the body, as it might induce a general sycosis. Should even this last-named remedy prove ineffective, then pyrogallic acid and chrysarobin (in a two to ten per cent. salve) should be tried.—*Therapeutische Monatshefte*, January, 1889.

Some Indications for Pleurotomy.—DR. CARDARELLI (*Il Progresso et La Rasegna di Scien. Med.*, October, 1888) is of the opinion that before performing a pleurotomy, one should first be certain of the existence of the pleuritic exudation, as well as of the quality of the same. To determine this, an exploratory puncture should be made. This done, four conditions remain in which recourse to thoracocentesis is essential: 1st. The presence of an excessive quantity of liquid in the pleura threatening asphyxia. 2d. When the pleural cavity is completely filled, but the patient does not suffer. 3d. When the liquid is purulent, but the patient's condition nevertheless satisfactory. 4th. When there is hydropneumothorax with heart and respiratory trouble due to compression of the vena cava from the pleural exudation.

Two conditions yet remain in which intervention would be justifiable: 1st. In a pleurisy which has been cured, but where a small quantity of liquid still remains. 2d. In an acute pleurisy with high fever, great pain, and rapid formation of the exudation.

In these two last-named conditions the author never hesitates to perform pleurotomy. If a fistula remains, he performs Estlander's operation, but in the majority of cases this even has been found unnecessary.—*L'Union Médicale*, December 27, 1888.

Transfusion in Carbonic-oxide Poisoning.—A workman who had inhaled the vapor of burning coals was taken to the Charite lately. All efforts to restore consciousness having failed, Professor Leyden ordered the injection of two hundred and fifty cubic centimetres of blood, taken from another patient, into one of the veins of the right arm. The patient showed signs of life five hours after the transfusion, then slept for about ten hours, and awoke in excellent spirits. His further recovery was rapid, and he is now quite well.—*Lancet*, January 5, 1889.

Creolin in Ophthalmology.—DR. O. PURTSCHER, of Klagenfurt, gives in the *Centralbl. f. pr. Augenheilk.* his results obtained with creolin in the treatment of diseases of the eye. A one per cent. solution dropped on the conjunctiva of a normal eye produces a sensation of severe burning, which results in the eyelids being closely pressed together. This, however, is only momentary, the lids are soon reopened and large tears flow forth. After three or four minutes the irritation will have subsided entirely, save for a slight conjunctival irritation, which also soon passes off. Hence the author recommends the use of cocaine before the application of creolin.

1st. In simple conjunctivitis, the results, as a rule, were good, especially in congestive catarrh, and in those forms complicated with inflammation of the corneal margin.

2d. In conjunctivitis phlyctenulosa, the combined results of creolin with cocaine were admirable, especially in photophobia and scrofulous blepharospasmus.

3d. Success was most marked in the papillary form of trachoma, the author having never seen such marked resolution of the papillæ from caustic treatment, as from that by creolin.

4th. In blennorrhœa of the lachrymal passages, improvement was observed in many cases.

5th. In all forms of keratitis with ulceration the deep ulcers healed rapidly; also ulcers with small hypopium stood the creolin treatment admirably.

6th. In parenchymatous keratitis the vascular growth was speedily arrested.

The author concludes that creolin is a powerful and valuable antiseptic, and at times to be preferred to the sublimate. It possesses another advantage in being non-poisonous, a fact which has lately been demonstrated by Dr. Eisenberg.—*Centralbl. f. d. ges. Therapie*, January, 1889.

Dropsy of Pregnancy.—DR. WALTER S. A. GRIFFITH, in an article upon this subject, gives the following advice:

"Treat the patient as a case of acute nephritis with dropsy; if there is no distinct improvement within a reasonable period (from two to four weeks), and with less delay if the dropsy increases, empty the uterus. The best method for doing this is by the introduction of a clean bougie, leaving it in until labor is established; a couple of five-grain doses of quinine being given at the end of twenty-four hours, if the uterus needs further stimulation."—*British Med. Journal*, Jan. 12, 1889.

Relative Value of Opium, Morphine, and Codeine in Diabetes Mellitus.—DR. THOMAS R. FRASER, in a paper on this subject, concludes as follows: The evidence seems to indicate that codeine is a less powerful remedy in diabetes than either opium or morphine, and to confirm the view that in its therapeutic value it ranks as a weak or diluted morphine.

The conclusion receives an importance (no doubt a subsidiary one) from the circumstance that codeine is about three times as expensive a substance as morphine. The great demand for it has led to its being manufactured from morphine so largely, that probably one-fourth of the codeine in the market is an artificial substance. When we consider the large doses that are required in diabetes mellitus, and the generally protracted duration of this disease, we are, I think justified in asking for more clear evidence of its superiority over morphine than has as yet been produced.—*British Med. Journal*, Jan. 19, 1889.

Common Salt in Nervous Affections of the Stomach.—DR. BATROM has lately employed common cooking salt in the treatment of migraine, and DR. NOTHNAGEL has recommended the same in the treatment of epilepsy. DR. CERNÉ attributes his success in the treatment of the first affection with this remedy, to an increase of the hydrochloric acid of the gastric juice. In a case of gastralgia and migraine, in which the treatment simply consisted in augmenting the quantity of salt in the food, he noticed that the dyspeptic symptoms and stomachal pains disappeared entirely.—*La Normandie médicale. Revue Thérapeutique*, December 15, 1888.

Atrophic Coryza.—DR. E. J. MOURE (*Journal of Laryngology and Rhinology*, November, 1888), after going very fully into the etiology and pathology of this condition, lays down the following rules for treatment:

A first irrigation of the nostrils made with one or two litres of tepid sulphurous water, to which is added either chlorate of potash, bicarbonate of soda, or borax, in the proportion of a teaspoonful to the litre. This is followed by a second irrigation, consisting of half a litre of tepid water, with the addition of a tablespoonful of the following fluid:

Carbolic acid	20 parts.
Glycerine	100 "
Alcohol at 90°.	50 "
Water	350 "

In order that the patient may not get accustomed to this solution, he substitutes chloral, resorcin, salicylic acid, etc., for the carbolic acid every month. After the douches, the patient ends the treatment by spraying the nostrils or insufflation of fine powder. For spraying he uses:

Carbolic acid	2 parts.
Resorcin (crystals)	3 "
Glycerine	50 "
Water	300 "

or

Camphor	8 parts.
Tinct. iodi.	10 "
Tar	12 "
Alcohol at 90°.	100 "
Water	200 "

To be warmed, and used to moisten the nose for one or two minutes after spraying.

Nasal douches must be carefully directed toward the naso-pharynx, and not up toward the root of the nose. They should be used tepid, and in small stream.

Thymol, Moure does not like, as it is painful, and not certain in its action. Surgical treatment he entirely discards, and Gottstein's tampons he has not found valuable, and very inconvenient.—*Bristol Medico-Chirurgical Journal*, Dec. 1888.

The Treatment of Scarlet Fever by Mercuric Iodide.—DR. PURDY, at a meeting of Leeds and West-Riding Medico-chirurgical Society, referred to Dr. Illingsworth's original paper recommending this treatment and the support given to it by Dr. Clement Dukes, of Rugby. He stated that he had tried it in more than fifty cases, during several epidemics, and was surprised at the results. In spite of the disease in one epidemic being of very severe character, there was only one fatal case, and that was dying when first seen. After giving the drug the temperature fell rapidly, and the patient seemed well in about three days, desquamation being very slight. The average period during which his cases were isolated was only eighteen days. He had seen no cases of infection from convalescents, and there were no lingering sequelæ. In one case a child was ill for five days, the diagnosis being uncertain; then the mother and several children sickened with evident scarlatina, two being very ill, with sloughs in the neck, but all made a good recovery, and were perfectly well before the first child had ceased peeling. The formula used was liq. hydr. perchlor. ℥j, pot. iodid. ℥ss, syrup.

ad ℥viij. Half an ounce to be taken every one, two, or three hours, according to circumstances. Several of his friends had tried this treatment but with less good results, owing, he believed, to the treatment not having been begun early enough, or the doses being insufficient.

MR. HICK said that he had treated in the Leeds Fever Hospital fifty cases with mercuric iodide. Except that there were more cases of nephritis than usual, he could detect no special effect from the use of the drug. He had treated recently three series of eight cases each simultaneously, with iron, mercuric chloride, and a *placebo*, and, on the whole, the latter series did best. He had tried the treatment also in typhus, typhoid, and small-pox, but with no result.—*British Med. Journal*, Jan. 19, 1889.

Suppositories for Cystitis.—

℞.—Iodoform . . . . 1¾ grains.
Extract of hyoscyamus . . 1 grain.
Cocoa-butter . . . . 45 grains.—M.

Make one suppository and introduce high up into the rectum.

The bladder should be washed morning and evening with lukewarm water. If there be any urethral irritation, a pill containing 1¾ grains of terpin should also be taken morning and evening.—*Journal de Médecine*, January 6, 1889.

Strophanthus in Pneumonia with Threatened Heart Failure.—DR. GRATZ (*Centralbl. f. klin. Med.*, No. 45, 1888, and *Münch. med. Wochenschrift*, p. 125, 1888) says, that at the Policlinik, at Erlangen, Dr. Pentzold has employed strophanthus in fifteen cases of severe pneumonia, with symptoms indicating heart failure. He gave the five per cent. tincture, in doses of ten drops, three times daily, and with very satisfactory results, as shown by an improvement in the general condition, slight decrease of the breath and pulse frequency, and especially a decrease in the irregularity of the heart's action. No unpleasant effects from the drug were observed.—*Medical Chronicle*, January, 1889.

Parenchymatous Injections of Distilled Water in the Treatment of Chronic Tumors of the Spleen.—DRS. MURRI and BOARI, being convinced that the benefit derived from arsenic injections in the treatment of tumors of the spleen is not due to the arsenic, but rather to the fluid injected, treated a case of splenic tumor, in a man of twenty, suffering from chronic malaria, by daily injections of one Pravaz-syringeful of distilled water into the parenchyma of the spleen. After two months of this treatment, the organ was considerably reduced in size. Drs. Murri and Boari recommend this treatment highly, which, if carried out carefully, is not followed by evil consequences.—*Wiener med. Presse*, Jan. 13, 1889.

Treatment of Acute Diffuse External Otitis.—DRS. MIOT and BARATOUX prescribe, when the secretion is excessive, the following injections:

℞.—Bicarbonate of sodium . . 5 parts.
Water . . . . . 1000 "

or

℞.—Boric acid . . . . . 1 part.
Water . . . . . 35 parts.

or

℞.—Bichloride of mercury . . . 1 part.
Water . . . . . 200 parts.

—*Revue Gén. de Clinique et de Thérapeutique*, January 16, 1889.

Treatment of Pruritus of the Vulva.—If the affection is an acute one, a lotion containing a small quantity of bromide of potassium or chloral is of use. It is preferable to have the lotion warm rather than cold.

When the acute stage has passed, the following lotion should be applied:

℞.—Water . . . . . 300 parts.
Sublimate . . . . . 1 part.
Alcohol . . . . . q.s.

In chronic cases Dr. Guéneau de Mussy prescribes the following ointment, to be applied to the vulva two or three times daily:

℞.—Glyceride of starch . . . ℥v.
Bromide of potassium . . . 15 grains.
Subnitrate of bismuth . . . 15 "
Calomel . . . . . 6 "
Extract of belladonna . . . 3 "

or

℞.—Infusion of mallow . . . 1000 parts.
Cherry-laurel water . . . 50 "
Borate of sodium . . . 10 "

This lotion to be followed by the application of the following powder:

℞.—Powdered lycopodium . . . 30 parts.
Subnitrate of bismuth . . . 10 "
Belladonna-root . . . . 2 "

The following ointment is also of service:

℞.—Diachylon ointment } . . . equal parts.
Olive oil }

For an eczema of the vulva, Dr. Lusk recommends the following lotion:

℞.—Bicarbonate of sodium . . 8 parts.
Bicarbonate of potassium . . 4 "
Glycerin . . . . . 6 "
Tincture of opium . . . 8 "
Water . . . . . 250 "

Applications of a solution containing cocaine might also be tried:

℞.—Glycerine . . . . . ℥vjss.
Cocaine . . . . . 15 grains.
Chlorhydrate of morphia . . 1¾ "

In very obstinate cases Dr. Martineau employs sublimate baths; made by adding the following solution to a bath:

℞.—Water . . . . . 190 parts.
Sublimate . . . . . 20 "
Alcohol . . . . . q.s.

While these local applications may all be of service, one must not omit constitutional treatment which often relieves indirectly the cause of the pruritus.—*Revue Générale de Clinique et de Thérapeutique*, Jan. 16, 1889.

Decussation of Fibres of Voluntary Movement.—DR. BROWN-SÉQUARD in an exhaustive paper upon this subject reaches the following conclusions:

1st. The fibres of the anterior pyramids which cross and overlap each other at the inferior portion of the bulb, can be the only, or at least the principal, channel for the transmission of voluntary motion.

2d. The protuberance, as supposed by a number of physiologists, must be the principal point of decussation of the fibres which control the voluntary movements of any member.

3d. The decussations of the fibres for voluntary as well as for reflex motion of the limbs are found along the entire length of the cerebro-spinal centre.

4th. It is wrong to assume that paralysis due to unilateral lesions of the bulb or other parts of the encephalum, in man as well as in animals, depends upon the destruction of localized centres or upon groups of fibres serving only for voluntary motions.—*Archives de Physiologie*, January, 1889.

Male Sterility and Gynecology.— DR. FÜRBRINGER, of Berlin, has written some important observations on this subject in the *Deutsche Med. Wochenschrift*, No. 28, 1888. He believes that sterility in the male is far more frequently the cause of barren marriage than is generally believed to be the case. Aspermatismus is associated with complete impotence, but azoöspermia, or absence of spermatozoa in the semen, a condition by no means rare, may exist with perfect potency, and on that account is very easily overlooked. With few exceptions, azoöspermia is caused by obliteration of part of the seminal ducts. This condition is generally caused by double gonorrhœal epididymitis, or inflammation of the vas. After that malady, the chances are, Dr. Fürbringer has calculated, nine to one that azoöspermia will follow. Prognosis appears to be hopeless when the condition in question is not discovered until three or four months after the onset of the local inflammation. The chief importance of the management of the case lies in accurate diagnosis. True aspermatism is traced by Dr. Fürbringer to arrested development of the ejaculatory ducts. He declares that in several cases of sterile marriages under his own observation the unfortunate wife had been sent from physician to physician, or from hospital to hospital, and her cervix divided, or her endometrium scraped, until a glance at the microscope proved that nothing was wanting to insure the blessing of children, excepting spermatozoa. Dr. Fürbringer's observations are worthy of consideration. No doubt the increase of temperance involves the relatively greater frequency of those forms of gonorrhœa where the earlier symptoms are very mild. Hence the first stages may now be as much neglected by patients as they have ever been wont to neglect later stages. The more a case of gonorrhœa is neglected, the greater will be the chance of serious secondary complications.—*British Med. Journal*, Jan. 19, 1889.

Treatment of Typhoid Fever with Naphthol.—DR. GENNARO PETTERUTI gives in the *Giornals internaz delle scienze medische*, No. 10, his results obtained with naphthol in the treatment of typhoid fever. From his observations he concludes that naphthol may be administered in doses up to sixty grains daily. The only unfavorable symptoms observed during its administration were a more or less severe burning sensation felt while urinating, and a dark brown coloring of the urine. This discoloration of the urine begins five hours after the remedy has been taken and lasts throughout the treatment, and is, no doubt, due to the absorption of a certain quantity of naphthol from the intestines, which finds its way into the urine. Diarrhœa was rarely observed.

Not only does naphthol possess an antipyretic action like antipyrin, thallin and other antipyretics, but it also has a direct healing influence upon typhoid fever. In the author's cases a reduction of temperature followed the administration of naphthol, which did not rise again even after the remedy was withheld. The fall in temperature which begins between the second and third day continues till it has reached the normal.

The advantage of naphthol over other antipyretics consists in its being well borne by the intestinal mucous membrane and in being absorbed in small quantities only by the intestinal canal, thus remaining for a longer time in contact with the affected parts.

With children under four years of age, the author began treatment with daily doses of fifteen grains, which was at no time allowed to exceed thirty grains, while adults for the first few days were given four doses of eight grains each, and later on eight doses daily of the same quantity, the interval between each dose being one hour.—*Wiener med. Presse*, January 6, 1889.

Creolin as an Antiseptic.—DR. L. A. STIMSON, at a recent meeting of the New York Surgical Society, showed a sample of pure creolin, and also one of a two per cent. mixture in water. It was a dark, viscid liquid with a tarry odor, insoluble except in alcohol, a two per cent. aqueous mixture appearing as a fine emulsion. He had been much troubled by the fact that secretions from wounds readily underwent decomposition under dressings of sublimate gauze, and had thus been led to try creolin. He had now employed it for two months at the New York and Chambers' Street Hospitals, with very satisfactory results, using ordinary purified gauze wrung out in a two per cent. aqueous mixture. The drug was rarely irritating to the skin. It was not only a good antiseptic, but it also arrested parenchymatous bleeding and hastened cicatrization. When applied to ulcerated cancerous surfaces, it was a powerful deodorizer. Chemically it closely resembled a cheap patented disinfectant, sold under the name of "soluble phenyl," but the latter was of somewhat thinner consistence; creolin contained no carbolic acid.—*New York Medical Journal*, Feb. 2, 1889.

Poisoning with Hydrochloric Acid.—DR. MAURICE LETULLE and HENRY VAQUEZ from numerous observations on persons poisoned with hydrochloric acid, made during life and at post-mortem, reach the following conclusions:

1st. Hydrochloric acid in poisonous quantities produces severe gastritis with embryonic proliferation and extensive cellular necrobiosis.

2d. Experience and clinical observation prove the frequency and danger of penetration of the caustic liquid into the respiratory passages, during the efforts at regurgitation or vomiting which follow the ingestion of the poison.

3d. Hence these efforts at vomiting, should be, if possible, prevented and counteracted by promptly washing out the stomach with appropriate solutions.—*Archives de Physiologie*, January, 1889.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, FEBRUARY 9, 1889.

PUNCTURE OF THE ABDOMEN FOR EXCESSIVE TYMPANITES.

THAT it is most desirable and expedient to relieve distressing or dangerous tympanites all will agree, but the same unanimity of opinion will not prevail when we come to consider by what means this shall be accomplished. Of surgical methods there are two: the rectal and œsophageal tubes, and puncture or aspriation of the intestines or stomach through the abdominal parietes. These latter procedures have recently been most elaborately set forth and heartily commended in a valuable historical and clinical monograph from the pen of Dr. John W. Ogle, of London. In this work the author has collected from the experience of his hosts of friends and colleagues a vast array of cases and clinical material. Perusing the mass of facts therein contained we find that, as a rule, surgeons are not zealous in advocacy of the measure whilst medical men, including Ogle himself, are almost all pronounced in its favor. We, ourselves, have had small but salutary experience with the operation, and, whilst acknowledging our previous dislike to it upon theoretical principles and hearsay of a few instances in which unfortunate consequences were said to have followed its employment, must, in the absence of larger personal experience, yield to the greater weight of contrary evidence presented by Ogle, and agree that, properly performed in judiciously selected cases, the operation of puncture of the abdomen for tympanites is comparatively safe and expedient. As an euthanasic measure it is always justifiable.

From Ogle's work we cull many of the following facts regarding the range of application and mode of performing the operation. Puncture will effectively relieve distention of the colon and stomach, and some cases of small intestine inflation if the calibre of the latter is greatly enlarged; otherwise tapping the small bowel will usually prove unavailing, because of its numerous kinks and twists. The stomach should only be punctured when obstruction of the œsophagus prevents its relief by the tube. Incurable cases of bowel obstruction are robbed of some of their most distressing symptoms by puncture; whilst cases of curable obstruction are much more apt to be spontaneously reduced after the distended bowel and impeded heart and lungs have been relieved by aspiration of the intestines. Drugs likewise, when before unabsorbed and powerless, will often be taken up and begin to act copiously upon the intestines so soon as distention is relieved.

To perform the operation, the abdomen should first be made technically clean by the use of soap and antiseptics. Then into the most prominent coil of bowel presenting, a trocar is plunged until it enters the lumen, when a rush of gas will take place through it. The trocar should be the very smallest available, and not triangular or spear-pointed, but round, that bloodvessels shall not be wounded and that the intestinal mucous membrane shall most effectively close the opening in the bowel thereby made. The aspirator jar is by no means necessary, for in most cases the gas will be rapidly forced out by the intra-abdominal pressure. When all gas has been discharged that will flow out, a little water is injected through the trocar to cleanse it, and it is then withdrawn by a quick motion; and the minute abdominal wound immediately sealed with such a dressing as iodoform and collodion. If large-sized trocars are employed, there is great danger of fecal extravasation, either at once or when distention recurs. Several or many punctures at various points over the distended bowels may be necessary for entire relief, and repetition of the operation may be required to remove re-accumulations due either to formation of more gas in the colon or to its advent from the small intestine. The puncturing instrument must be thoroughly cleansed between punctures, by boiling, if more than one is required.

According to Ogle's large collection of cases, extravasation after such puncture practically never

occurs nor do adhesions form, subsequent operation becomes more dangerous or unpromising, or other noxious effects follow.

We recall a case which was suffering from impaction of a great number of the bones of pig's feet in the lower colon, in which all purgatives and clysters had refused to act, and the distress and cardiac danger were so great that we felt compelled to insert hypodermatic needles into various points along the course of the immensely distended colon. Gas rushed through these for about fifteen minutes, when the colon had become entirely collapsed. Within a very short time the accumulated purgatives began to act vigorously and the mass of obstructive material was soon dislodged, and passed by rectum. No untoward results followed and the patient was almost immediately cured.

THE SEPARATION OF THE SICK FROM THE INDIGENT POOR.

ACTING in accordance with the principles which have governed the growth and development of the great hospitals of the world, to which THE NEWS drew attention in its issue of January 12th, the authorities of Philadelphia are about to remove their indigent poor, not hospital patients, to a suitable almshouse, thus affording the city hospital much needed additional space.

The advantages of applying the funds of a city appropriated for the care of the sick to them only, and reserving for chronically disabled pensioners a style of maintenance adapted to their condition, have been demonstrated in European cities and in some American institutions. From the standpoint of medical science such a policy results in placing the largest available clinical material under the observation of the profession, in securing for hospital patients the best professional skill, and in advancing the cause of medical education.

The Philadelphia Hospital is probably the oldest on this continent, and affords a large field for clinical study. It is a curious fact that many of the oldest hospitals of the world exhibit the lowest death-rate, and are the scene of the greatest achievements of medicine and surgery. With the present knowledge regarding infective agents and the means for destroying them, large hospitals are as safe as the isolated dwelling, and when the systematic care and skilled treatment which they afford are considered they are more favorable fields for medical science than the dwelling.

American cities should adopt universally the principle of discrimination in the expenditure of public funds for the indigent; the sick should receive the most skilful and scientific treatment available, and afford opportunities for clinical study; the chronic pensioner should be maintained in the neighborhood of a city, and his labor utilized if possible. In this manner the public hospitals of the country will best further the interests of the State and the profession.

DR. HOLMES'S GIFT.

WE mentioned in last week's issue of THE MEDICAL NEWS the fact that Dr. Oliver Wendell Holmes had given his medical library to the Boston Medical Library Association. The oldest book of this collection of a lifetime was written in 1490, and the latest in 1887. In parting with these old companions, Dr. Holmes does so with a grace that marks everything that he puts his hand to.

"These books," says he, "are dear to me; a twig from some one of my nerves runs to every one of them, and they mark the progress of my study and the stepping-stones of my professional life. If any of them can be to others as they have been to me, I am willing to part with them, even if they are such old and beloved comrades." Bearing in mind that these are medical books chiefly of which Dr. Holmes is speaking, his warm praises become an encouragement to publishers to put forth the best, and only the best, books on the healing art.

Another reflection, a little tinged with sadness, is in the likeness in this act to that of a tired workman putting away his tools. Dr. Holmes is rapidly approaching his eightieth birthday, and these books of his are no longer needed in the period of retirement for which he is preparing to spend the remnant of his days.

While it cannot be said that the best of Dr. Holmes's intellect has been given to medicine, he has always been so loyal to her interests and so prompt in her support, that she has no feeling of jealousy to gratify because of the immortal honors he has won in other fields, and we believe that no class of readers of Dr. Holmes's works of wit and fiction has been better fitted for the enjoyment of them than have been his foster-brethren of the healing guild. Long may his years be in the land, and full of honor and free from all physical ill.

LAST Tuesday, the Trustees of the University of Pennsylvania filled the vacant chairs in the Medical

Department by the election of Dr. J. William White to the Professorship of Clinical Surgery, and Dr. John Guitéras to that of Pathology and Morbid Anatomy.

Dr. Guitéras is a native of Cuba, where he received his preliminary education, graduating from the Medical School of the University, in 1873. In 1879 he was appointed by the President of the United States a member of the Havana Yellow Fever Commission, and took charge of the investigations in morbid anatomy. In 1880 he was appointed to the Marine-Hospital Service. He was ordered by the Government to investigate epidemics of yellow fever in Vera Cruz, 1883; Key West, 1887; and Florida, 1888. Dr. Guitéras has lectured in various medical colleges, and has made valuable contributions to medical science. In order to accept the Chair of Pathology, he will resign his commission as Passed Assistant-Surgeon of the United States Marine-Hospital Service.

Dr. White was born in Philadelphia, and graduated in Medicine at the University in 1871. He is surgeon to the Philadelphia, German, and the University Hospitals, and has been a frequent contributor to the medical journals. He was the first Director of Physical Education in the University, and was largely instrumental in placing this department on a scientific foundation. Dr. White was also prominent in the work of introducing training schools for nurses in the University and Philadelphia Hospitals.

The Trustees of the Johns Hopkins Hospital have decided to formally open the Hospital on the first of May, and they have confided its organization to President Gilman, of the University. We understand that for one year, at least, President Gilman will reside in the Hospital, and exercise a close personal supervision over its executive management.

Great credit is due to the physicians who resisted pressure from high sources and declined to certify falsely as to the cause of death of the Archduke Rudolph. Professor Hoffmann, in addressing the University students last Monday, said that whatever rumors might be circulated, and whatever assertions might be made, he could declare, with a clear conscience, that he and his colleagues, in their report of the autopsy on the Crown Prince, signed nothing but what they could answer for with their honor.

REVIEWS.

Clinical Lectures on Certain Diseases of the Nervous System. By J. M. Charcot, M.D. Detroit: George S. Davis, 1889.

With the exception of Claude Bernard and Brown-Séquard, the name of Charcot shines, and has shone for years, par excellence, as the best exponent of medical thought in France. Even yet, in his early old age, this greatest of neurologists, still gives, and we hope will continue to give, practical lessons to the profession, which are generally far more wide-reaching in their bearings than is often thought. As a consequence, every one is glad to hail a translation of Charcot's lectures or books, and always finds on their pages much food for thought.

In this little book the subjects of spiritism (*sic*) and hysteria, and the treatment of the latter by isolation, choreiform movements and tremblings, and rhythmical chorea, are carefully considered in the first three chapters; while in Chapters IV., V., VI., VII., and VIII, the study of muscular atrophy resulting from articular lesions, contractions of traumatic origin, painless tic of the face, muscular atrophy from articular rheumatism, and hysteria in the male are likewise brought vividly before the reader. The book is made the more interesting by the insertion of a short biography of Charcot by the translator, Dr. Hurd, and this alone is worth the cost of the volume, showing, as it does, not only the character of the man and the breadth of his thought and labors, but, in addition, the fact that by diligence and thought he has reached a plane of professional favor and esteem on which few other medical men can stand, and which may well serve as an example to those who value the goodwill and admiration of their fellows.

Pulmonary Consumption Considered as a Neurosis. By Thomas J. Mays, M.D., Professor of Diseases of the Chest in the Philadelphia Polyclinic. Pamphlet, 8vo. pp. 63. Detroit: George S. Davis, 1888.

This brochure consists of two lectures, which were delivered at the Philadelphia Polyclinic in the course of 1888–89. The author holds that in consumption the lung affection is only "a special manifestation of the disease which invades the whole body; and that all its diversified symptoms, such as fatigue and exhaustion, anorexia, dyspepsia, wasting, dyspnœa, sweating, diarrhœa, hæmoptysis, intercostal tenderness, hoarseness, aphonia, and œdema, are not the consequences of pulmonary disease, as is commonly believed, but in all probability find a common bond of union in a general disorder of the peripheral nervous system.

"That it is possible for a neurosis of the vagus to give rise to all the lesions which are generally found in phthisical lungs, is not beyond the bounds of legitimate reasoning, although it may not be demonstrable by experiment. For it has already been shown, as in the case of herpes zoster, that disturbed innervation is capable of leading to a catarrhal inflammation of the skin, and if a herpes or a catarrhal inflammation can be produced in the skin through nervous influence, it is also within the limits of logic to hold that the same may occur in a mucous membrane,—the morphological counterpart of the skin. And, after the catarrhal con-

dition is once permanently established in the bronchial tubes and in the air-cells, all the other pathological changes which are characteristic of phthisis follow as a necessary consequence. A catarrhal process in these surfaces implies a proliferation of epithelial cells, and, on account of the sacculated form of the alveoli, the catarrhal material, unlike on the free skin surface, where it may be removed as soon as it forms, is very liable to accumulate in and pack these structures and form small nodules, which are commonly, but erroneously, called tubercles. These smaller nodules coalesce and form larger masses, which finally impinge on the surrounding circulation, and thus cut off their own nutritive supply. After this takes place they undergo a cheesy degeneration, soften, communicate with a bronchus, are expelled, and leave a cavity behind."

As to treatment, the author holds that rest, absolute or an approach to it, is one of the most vital factors in the successful treatment of serious nervous disease, and he believes that "the prevailing opinions that consumptives must have plenty of exercise and fresh air are two of the greatest stumbling-blocks in the successful management of this disease."

OSTEOTOMY FOR ANTERIOR CURVATURES OF THE LEG. By DE FOREST WILLARD, M.D., Lecturer on Orthopædic Surgery, University of Pennsylvania. Pamphlet, 8vo. pp. 20.

THIS paper was read before the American Orthopædic Association at its meeting last autumn. Its author's views are summarized in the following conclusions:

1. Anterior tibial curves during the soft and springy stages may be corrected by manual rectification and the use of apparatus.

2. Braces are useless after hardening has occurred.

3. Manual fracture is the best and safest remedial operation in young children.

4. Instrumental fracture, or osteoclasis, is not as safe or effective as osteotomy.

5. Aseptic simple osteotomy for all moderate degrees of curve, and cuneiform section for very severe grades, give almost uniformly good and speedy results, without suppuration. Subcutaneous section by the saw is also a reliable operation.

6. Plaster of Paris is the simplest and most effective material for securing accurate position and maintaining absolute fixation. By its use the delay and injury incident to suturing the ends of the bones are avoided.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN OBSTETRICS AND GYNECOLOGY.

JOSEPH E. JANVRIN, M.D., CHAIRMAN.

Stated Meeting, January 24, 1889.

DR. H. J. BOLDT read a paper on

THE TREATMENT OF SUPPURATIVE DISEASE OF THE UTERINE APPENDAGES.

At the present time, he said, there was much difference of opinion in regard to the justifiability of surgical interference in diseases traced to the uterine appendages, and while some gynecologists had gone to extremes in operating, others had gone to extremes in the opposite direction, instead of keeping the medium and selecting cases for operation with great care. Cases of disease of the uterine annexa might be roughly divided into three groups: 1. Those in which an operation is altogether unjustifiable. 2. Those in which it is the wiser course to keep the patient under treatment for a time, in order to observe what benefit may thus be derived, before deciding finally as to the advisability of operating; and 3. Those in which delay is not only unadvisable, but actually fraught with danger.

His special object was to argue the necessity of abdominal surgery, as a rule, in the disease of the Fallopian tubes known as pyosalpinx; excluding certain exceptional cases to be noted hereafter. This plea for operative interference was based upon a number of cases coming under his own observation, and the histories of which he then proceeded to narrate.

CASE I.—April 15, 1887. Theodora K., thirty-six years of age. Married sixteen years; one child, born fourteen years ago. Labor was instrumental, and followed by metritis and peritonitis. Her illness dates back to this confinement. During the last five years, her pains have increased, and she has had a number of attacks of local peritonitis. Five years ago she was infected by her husband with syphilis, from the secondary effects of which she is still suffering; and the increase of the pains thus corresponds with the syphilitic poisoning. Having described the symptoms and the physical signs, he said that the diagnosis made was double salpingo-oöphoritis syphilitica with endometritis, and an operation was advised if improvement did not result from a few months' treatment. On May 15th a fresh attack of pelvic peritonitis occurred as the result of violent physical exertion. On May 20th he was summoned to the patient, who was suffering intense pain, and found her then with a general peritonitis. At this time the tubes, which could formerly be distinctly mapped out by the fingers, had lost their contour, and in the position occupied by them a general fulness was found; while the examination caused excessive pain. It was therefore apparent that the tubes, which had been distended with pus, had ruptured, and a general peritonitis had thus been excited. The patient was removed to the hospital on the same day, but, unfortunately, he did not make up his mind to operate until the following afternoon, when an experienced colleague concurred in the diagnosis and the course to be pursued. At 9 P.M., he performed abdominal section, when the diagnosis made was confirmed. The abdomen was thoroughly washed out, and a Sims's drainage tube placed behind the uterus, washings being made afterward at frequent intervals. For thirty-six hours the patient did well, but she then began to sink, and sixty hours after the operation died in collapse.

CASE II.—Kate L., aged twenty-nine, single, nonpregnant, seen in consultation May 25, 1887. She gave the history common to cases of salpingitis previous to her present illness. On April 21st she was suddenly seized with severe pain in the lower part of the abdomen, which gradually increased in intensity for some time, and then began to subside. On May 23d she again became worse, and developed a high temperature. On examination it

was found that she had general peritonitis and was much emaciated. The seat of the most intense pain was to the right of the uterus, where a fulness with slight fluctuation was appreciable. The diagnosis was septic peritonitis from the rupture of the right Fallopian tube, in which pyo-salpingitis had previously existed; and this was confirmed when laparotomy was performed at the hospital on the following day. The abdominal cavity was thoroughly cleansed of pus, but the hemorrhage was so profuse from the points where the adhesions were separated that no attempt was made to introduce a drainage-tube; and the patient's condition was so poor that time could not be spared to look up and secure all the bleeding points. Instead, that part of the pelvis from which the hemorrhage came was tamponed with iodoform gauze. The peritoneum was separately closed, as in all Dr. Boldt's abdominal sections, with the exception of the lower angle where the tube protrudes, when the latter is used. The patient rallied remarkably well, the iodoform gauze tampon acting admirably as a drain and as a hæmostatic. Thirty-six hours afterward it was removed, and a hard-rubber double current drainage tube, through which the abdominal cavity was washed out, inserted in its place. Later she began to sink and on the fifth day she died. The autopsy showed diffuse nephritis, but the pelvis was perfectly clean, and there was found to be a decided diminution of the peritonitis.

CASE III. was that of a young woman twenty-three years of age, who had been married eighteen months, and had a child six months before she came under observation. The diagnosis was endometritis and double pyosalpinx of puerperal origin. Both tubes were felt enlarged, and the right ovary was about the size of an English walnut. The uterus was displaced anteriorly and was very tender, and the cervix was lacerated bilaterally. On June 12th he was suddenly summoned to see the patient, who had been seized early in the morning with a very severe attack of abdominal pain, accompanied with vomiting. She was suffering from slight shock and there was marked tenderness over the entire abdomen, but no evidence of intense general peritonitis. The enlarged tube could be no longer felt on the right side, and the diagnosis of rupture of a pyosalpinx was made. Within two hours after first seeing the patient he opened the abdomen, and the diagnosis was confirmed. Peritonitis had already begun, but after thoroughly cleansing the abdominal cavity he closed the wound, using no drainage; and the patient made an uninterrupted recovery.

CASE IV. was also that of a young woman with double pyosalpinx of puerperal origin. Operation was advised but the patient did not consent. On July 27th she was attacked with intense abdominal pain and tympanites, and the diagnosis of commencing peritonitis from rupture of one or both tubes was made. Abdominal section was promptly performed, the cavity thoroughly cleansed, and the wound closed. Although the peritonitis had made considerable progress for such a short time, the patient made a complete and rapid recovery. In this instance one tube had ruptured, causing the attack, and the other became ruptured during removal.

In commenting on these cases Dr. Boldt expressed great regret at not having operated earlier on the first case, and stated that twice within the past two years he had seen cases on the post-mortem table which had died of purulent peritonitis directly attributed to a ruptured pyosalpinx. These cases he also related: The first came to his clinic in March of last year, and he at that time advised opening of the abdomen and removal of the uterine appendages. On June 30th he was summoned to the patient's house, where he found her suffering from general peritonitis. The immediate operation was declined, and she died July 2d. In the second case the patient also developed general peritonitis, but recovered without an operation. His prognosis was guarded, however, as the tubes continued to enlarge after this. Subsequently she had a very sudden and sharp attack of pain in the right inguinal region, and when he reached the bedside he found her in agony, screaming with pain, cyanotic, and with a high temperature and feeble, frequent pulse. The diagnosis of rupture of the right tube was made, but as the patient rapidly improved under opiate treatment while the preparations were being made to operate, and it, therefore, seemed possible that an error had been made in diagnosis, it was decided, on consultation, to defer the operation at least to daylight. In two hours, however, she began to sink, and by morning operation was entirely out of the question, despite the free use of stimulants.

His conclusion was, that abdominal section cannot be too strongly urged in every case of active pyosalpingitis, from whatever cause it may arise, except in the rare instances where the uterine extremity of the tube is patent, so that pus can be squeezed out of the latter into the uterus; and excepting also those cases where the tubal disease is complicated with another disease which itself will probably destroy life in a short time.

As to the question of diagnosis, he thought that a careful observer, experienced in this line of work, would not often make a mistake. The conditions from which it was usually necessary to differentiate were hydro- and hæmato-salpinx; but if the tubes were much distended the question of ovarian or par-ovarian cyst had also to be taken into consideration. The history of the case was of the greatest importance in determining its true nature. While many gynecologists considered it unjustifiable to operate for hydro- or hæmato-salpinx, it was unfortunately an impossibility always to make the positive diagnosis before opening the abdomen; and, furthermore, he still adhered to the opinion, expressed by him two or three years ago, that even cases of hydro-salpinx should be operated on if they give rise to serious morbid symptoms which cannot be alleviated by other treatment, because the simple and inert liquid may take on purulent changes as the result of an inflammatory condition set up in the walls of the tube, or the extension of endometritis. It was also a fact that, in consequence of their openings being blocked, the tubes might become distended to such an extent as to cause rupture with the possibility of fatal peritonitis resulting. He desired to lay special stress on the point that when we have reason to suspect active suppurative disease we should open the abdomen, from which, even if our diagnosis should prove wrong, not much harm would result to the patient.

If the diagnosis of pyosalpinx was correct, immense advantage was conferred upon the woman, since, in the first place, the operation, as a rule, removed the pain incident to the condition, and changed her from an invalid to a healthy individual; and, secondly, removed the danger of rupture of the tube and fatal peritonitis.

It was true that at the meeting of the American Gynecological Society in 1887 a prominent German operator had said that his mortality from salpingo-oöphorectomies was over twelve per cent., and that in his last published statistics this percentage was even somewhat higher; but it was to be borne in mind that the cases selected by him for operation were extremely unfavorable, since he waited very long and exhausted all other means of treatment before resorting to it. It was against this very long waiting that he would protest. Why let a patient suffer so long when from the history and the physical examination we are satisfied ourselves that she is suffering from a condition not amenable to non-surgical methods of treatment?

If in any case when pyosalpinx was supposed to exist, and laparotomy having been performed, it was found that hydro- or hæmato-salpinx was present, Dr. Boldt was very positive that the tube should be removed, notwithstanding the fact that it did not at the time of the operation contain pus, provided it was at some point firmly excluded from the effects of adhesive inflammation. In some comments on the second case included in the paper he said that, admitting that home care among the poorer classes was very much inferior to hospital nursing, he should not again expose a patient suffering from general peritonitis to the danger of removal to a hospital (which in this instance was four miles from the woman's residence), but take his chances of watching the case at home. The patient's condition being so very low, it was of paramount importance to operate as quickly and with the loss of as little blood as possible, and in this case the iodoform gauze, advocated principally in Germany, was used with much success; the many bleeding points and the broken-down condition of the tissues rendering it impossible to apply successfully ligatures or the hæmostatic process. Since that case he had several times had occasion to observe the efficiency of the gauze packing in profuse intra-abdominal hemorrhage in which every other allowable means known to him would have been a positive failure. In this instance the peritoneal cavity after the removal of the gauze tampon was dry and free from odor, and he now believed that if he had then finally closed the wound, not introducing any drainage-tube at all, the patient would have recovered.

In conclusion, Dr. Boldt said that no one could be more opposed than he to the indiscriminate removal of the appendages, which had unnecessarily unsexed so many young women. Even should pyosalpinx exist, if the distention of the tube was slight and gave rise to no morbid symptoms it was the wiser plan to wait, in the hope that the pus would become inert by undergoing cheesy degeneration. In other cases, where the question of operation arose, massage employed after the method of Brandt was an excellent means to diagnosticate the patency of the tube, and should a communication exist between the tube and uterus, it constituted, if properly employed, a very valuable adjunct in the treatment. It might be, however, a very dangerous procedure in this disease in the hands of an inexperienced manipulator.

Dr. Carl Zeiss, the celebrated optician, founder and owner of the great microscope factory in Jena, has just died at the age of seventy-three.

CORRESPONDENCE.

A SUCCESSFUL CASE OF PARTIAL LARYNGECTOMY FOR CANCER.

To the Editor of THE MEDICAL NEWS,

SIR: In writing you little more than a year ago, from Berlin, I described at some length an operation for partial extirpation of the larynx, performed by Hahn at the Frederickshain Hospital. The patient was a man, thirty-seven years old, a Mr. K., from Danzig, who had for some time been suffering with an ugly growth on the left vocal cord. He had consulted my friend, the well-known Dr. Tomwaldt, of Danzig, who, recognizing the nature of the growth, had sent him to Berlin. Having seen the operation itself, and having visited the gentleman several times subsequently, I was interested to know some of the particulars about *his death*, having read of it in several papers; but more especially had I noted it, since in Mackenzie's brochure, page 243, case 130, this patient was reported as *Dead—four weeks after operation.*

I spoke to Dr. Tomwaldt about the case, and expressed my regret, in reply to which he informed me, much to my surprise, that the man was not only *not dead*, but alive and perfectly well, and at the present speaking in Danzig.

The next day, through the courtesy of Dr. Tomwaldt and the gentleman himself, I had the pleasure of making a thorough examination of his throat, which is in good condition, with no sign of further trouble. Moreover, his voice is very fair, though, of course, hoarse.

Hahn removed, in this case, the entire left half of the larynx, the operation being very thorough, for the growth had been in a short time very active. The operation was performed November 9, 1887, and the patient has every prospect of a long life. Now at the time of the operation, the growth was infinitely larger than that in the throat of the Crown Prince, when Mackenzie operated in May, 1888.

That such a gross error as this should have been made in Mackenzie's book, is a matter of surprise.

Respectfully yours,

F. DONALDSON, JR.

DANZIG, POMERANIA, January 15, 1889.

THE WEST VIRGINIA MEDICAL ACT.

To the Editor of THE MEDICAL NEWS,

SIR: In your editorial (January 26th) on "States may Regulate the Practice of Medicine," based on the decision of the U. S. Supreme Court, in the case of F. M. Dent, you make a verbal error calculated to mislead.

In the section of our law classifying those permitted to practise, the second class were "those who have practised medicine in this State *continuously* for a period of ten years prior to the eighth day of March, 1881," not simply been in the practice of medicine *ten years* in the State, as *you* state it.

This class included some highly qualified medical men of advanced age, who in former years could not avail themselves of a collegiate education; as well as a large number of very poorly qualified men, who took up the practice of medicine without any qualifications whatever of study.

This class is rapidly being eliminated from the ranks of the profession as time goes on, by death and removal. So now virtually we have but two classes: First, "all who are graduates of a reputable medical school in the school of medicine to which the person desiring to practise belongs." Second, those who, not being such graduates, have passed examination before one of the State Examining Boards.

Gradually the requirements in these examinations have been raised, until now, I believe, a percentage of 85 of correct answers is necessary to pass the examiners; and the first course student finds it easier to go on and complete his course at college, than to obtain a certificate from the State Board.

Under the action of the law the status of the profession has been raised; our State virtually rid of the presence of itinerant quacks; and by an amendment passed in March, 1887, rid to a great extent of the itinerant vendors of medicines; such as delight to attend the presence of any gathering of people, as on Court days, etc.; also the bands of Indians under control of white vendors, etc., who, a few years ago, were visiting our towns, prescribing and evading the law, by professing to be simply selling their wares.

Perhaps some day we will advance a step farther and come into line with the mother State, Virginia, and require all to pass a State examination. Our State Board "may refuse certificates to individuals guilty of malpractice or dishonorable conduct, and may revoke certificates for like causes;" but cannot revoke certificates for unprofessional conduct, as resorted to *by charlatans* and *ignorant impostors*. We can only reach the travelling charlatan by our tax of fifty dollars per month, or fraction of a month, that he desires to practise in a county. If he becomes a resident physician, no matter how brazen his charlatanry, how *audacious* his lying advertisements, the State Board cannot reach him, as our legislature refused two years ago to allow unprofessional conduct as a cause of revoking a certificate. Perhaps some day we may arrive at that.

Even in Illinois the authorities have had trouble in enforcing that provision.

Respectfully,

W. H. SHARP, M.D.

VOLCANO, WOOD CO., WEST VIRGINIA,
February 1, 1889.

NEWS ITEMS.

A Medical Examiners' Bill.—The following bill has been introduced into the State Legislature of Pennsylvania:

An act to establish a State board of medical examiners and licensers, and to define the powers and duties of such board.

Section 1. Be it enacted by the Senate and House of Representatives of the Commonwealth of Pennsylvania, in General Assembly met, and it is hereby enacted by the authority of the same: That within six months after the passage of this Act, the Governor shall appoint a State Board of Medical Examiners and Licensers, consisting of nine members, three of whom shall serve for one year, three for two years, and three for three years, and hereafter he shall each year appoint three members to serve for three years in place of those whose terms then expire. They shall be graduates of some legally chartered college or university having the power to confer medical degrees, who shall have practised medicine or surgery for a period not less than five years, but none of whom shall be members of the faculty or staff of any medical college or university. Provided, that in the appointment of the said Board, the members shall be chosen from lists of names, each list containing the names of not less than eighteen registered physicians, submitted by the State Medical Societies of the Commonwealth of Pennsylvania. In default of the submission of any such lists, the appointments shall be made by the Governor at his discretion from among the registered physicians of the Commonwealth having the qualifications specified in this section. Each member of the said Board shall receive a certificate of appointment from the Governor, and shall file the same within thirty days with the Prothonotary of the Court of Common Pleas of the county in which said member is registered under existing law.

Section 2. The said Board shall be known by the name and style of THE STATE BOARD OF MEDICAL EXAMINERS AND LICENSERS OF THE COMMONWEALTH OF PENNSYLVANIA, and shall have a common seal and may make and adopt all necessary rules, regulations, and by-laws not inconsistent with the Constitution and laws of this Commonwealth, or of the United States, and shall have power to locate and maintain an office for the transaction of its business. Five members of the said Board shall constitute a quorum.

Section 3. Upon the organization of the said Board, it shall be determined by lot which three members shall serve for a term of one year, which three for a term of two years, and which three for a term of three years. Every appointment to fill a vacancy or vacancies in the said Board shall be for the unexpired term, and the said vacancy or vacancies shall be filled by the Governor within sixty days after notification of the same, in accordance with the provisions of Section 11 of this Act; and he shall have power to remove any member of said Board for criminal, scandalous, or dishonorable conduct.

Section 4. The said Board shall organize at Harrisburg upon the first Tuesday of January, A. D. 1890, and shall elect from its own number a President and a Secretary who shall also act as Treasurer, both of whom shall hold their offices for the term of one year, or until their successors are chosen.

Section 5. The members of the said Board shall each receive a salary not exceeding three hundred dollars per annum, to be paid out of the fees for examination. The Secretary and Treasurer shall receive an additional salary, to be fixed by the Board, and shall file with the President of the Board a bond in the sum of one thousand dollars for the faithful performance of his duties. The necessary expenses of the said Board shall also be paid out of the fees, except as provided in Section 12 of this Act, and any balance remaining from the fees after the disbursements herein specified shall be paid into the treasury of the Commonwealth.

Section 6. The Board shall examine all applicants for license to practise medicine or surgery in this Commonwealth, who are properly qualified according to the provisions of Section 7 of this Act; and no one shall be excluded or rejected on account of adherence to any special system of practice. It shall hold two stated meetings each year, one at Pittsburg on the first Tuesday in April,

and one at Philadelphia on the first Tuesday in May respectively, and may hold special meetings at such times as it may deem proper. All examinations, except as to manipulative procedures, shall be conducted in writing, and all examination papers, together with the reports and action of the Examiners thereon, shall be preserved among the records of the said Board for a period of five years, during which time they shall remain open for inspection at the office of the said Board.

There shall be examinations in anatomy, physiology, chemistry, toxicology, pathology, hygiene, principles and practice of medicine, surgery, and obstetrics, and each applicant, upon receiving from the Secretary of the Board an order for examination, shall draw by lot a confidential number, which he or she shall place upon his or her examination paper, so that when said papers are passed upon by the Examiners the latter shall not know by what applicant said papers have been prepared; and upon each day of examination all candidates shall be given the same set or sets of questions.

Section 7. Any person, on paying ten dollars to the Secretary of the said Board, and on presenting satisfactory proof of being over twenty-one years of age, of good moral character, and of having received a sufficient preliminary education, as defined by said Board, and a diploma from some legally incorporated medical college or university having authority to confer degrees in medicine, shall be entitled to examination by the said Board; and, in case of failure at any such examination, shall have the privilege of a second examination, without the payment of any additional fee.

Each applicant who shall have passed a satisfactory examination, shall receive from said Board under seal a license to practise medicine and surgery in the Commonwealth of Pennsylvania, and the said Board may at its discretion grant licenses without examination to persons holding licenses from similarly constituted Board of Examiners or Boards of Health in other Commonwealths.

Section 8. The Secretary shall record in a book to be kept for the purpose in the office of the said Board, the name and age, sex, residence, date, and place of graduation of each applicant, together with the date of examination, the examination number, the examination average on each branch, the general average, and date of issue of license, in case such license is granted. Said book shall be open to public inspection. And on or before the last day of December of each and every year, the said Board shall publish, or cause to be published, a list of the names and addresses of such persons as shall have received licenses from the said Board, within twelve months immediately thereto preceding.

Section 9. After the first day of February 1890, no person shall enter upon the practice of medicine or surgery in the State of Pennsylvania unless he or she has complied with the provisions of this Act, and shall have exhibited to the prothonotary of the Court of Common Pleas of the County in which he or she resides a license duly granted to him or her by the said Board of Examiners and Licensers, whereupon he or she shall be entitled upon the payment of one dollar to be duly registered in the office of the prothonotary of the Court of Common Pleas in said county; and any person violating the provisions of this Act shall be guilty of a misdemeanor, and upon conviction thereof in the Court of Quarter Sessions of the County where the offence shall have been committed, shall pay a fine of not less than fifty, nor more than five hundred dollars for each offence.

Section 10. Nothing in this Act shall apply to commissioned medical officers of the United States Army or Navy, or of the United States Marine Hospital Service, nor to any member of the house, or resident staff of any legally chartered medical college, or university, or hospital during his term of service therein; nor to any physician of other States meeting duly registered physicians of this State in consultation; nor to those practising dentistry exclusively; and nothing in this Act shall be construed to prohibit the practice of medicine and surgery by any practitioner who shall have been duly registered before the first day of February, 1890, according to the terms of the Act entitled "An Act to provide for the Registration of all Practitioners in Medicine and Surgery," approved the eighth day of June, 1881.

Section 11. For the purpose of this Act, the words "practise medicine or surgery," shall mean to treat or attend any person for money, gift, or reward.

Section 12. The sum of one thousand dollars is hereby appropriated to meet the necessary and legitimate expenses of the said Board for the year A. D. 1890.

Section 13. Section 4 of "An Act to provide for the Registration of all Practitioners of Medicine and Surgery," approved the eighth day of June, Anno Domini 1881, is hereby repealed.

CORRIGENDUM.

In our issue of December 29, 1888, in Dr. Dale's "Notes on the Use of Strophanthus," page 716, at the end of the tenth line, insert *not.*

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM JANUARY 29 TO FEBRUARY 4, 1889.

KILBOURNE, HENRY S., *Captain and Assistant Surgeon* (U. S. Army).—Will accompany Battery "E," First Artillery, changing station from Vancouver Barracks to Presidio, San Francisco, California, as medical officer, and, upon completion of this duty, will report to the commanding general Division of the Pacific, for further orders.—Par. 2, *S. O. 6, Headquarters Department of California, Vancouver Barracks,* January 22, 1889.

By direction of the Secretary of War, the leave of absence on surgeon's certificate of disability, granted HENRY G. BURTON, *Captain and Assistant Surgeon,* in Special Orders No. 19, January 24, 1888, from this office, is extended six months, on surgeon's certificate of disability.—Par. 8, *S. O. 22, A. G. O., Washington,* January 26, 1889.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING FEBRUARY 2, 1889.

SCOTT, H. B., *Passed Assistant Surgeon.*—Detached from the Naval Hospital, Mare Island, California, and granted one year's sick leave.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

THE EARLY RECOGNITION OF CANCER OF THE CERVIX UTERI.[1]

BY HENRY C. COE, M.D., M.R.C.S.,

PATHOLOGIST TO THE WOMAN'S HOSPITAL; ASSISTANT SURGEON TO THE NEW YORK CANCER HOSPITAL.

SOME apology may seem necessary for introducing a subject which is touched upon in most of the text-books on diseases of women, and with which we are supposed to be familiar. Having, through my connection with the New York Cancer Hospital, the opportunity of observing a considerable number of cases of incurable malignant disease of the cervix, I am constantly impressed with the frequency with which the mournful statement recurs in the histories of these unfortunates—that their attending physician never told them that there was anything serious the matter with them until their condition had become hopeless. The proportion of inoperable cases sent to hospital is so large, that it seems to me it is high time that the attention of the profession in this country should be called to the fact that we need not expect that our statistics of operations for the cure of cancer of the uterus will ever improve until the general practitioner learns to recognize the existence of the disease before it has reached a stage at which complete extirpation of the organ, if justifiable at all, offers little prospect of permanent relief. A recent German writer (Thiem) following out this line of thought, calls attention to the large number of operable cases treated at the Berlin clinic, as compared with those which come under the observation of surgeons in the smaller Continental cities, and attributes the difference to the fact that in the former the disease is recognized more promptly.

The marked impetus which has been given to the cultivation of skill in gynecological diagnosis has, unfortunately, not extended to the recognition of incipient cancer of the cervix. Cases of neglected ovarian cyst, even in remote country districts, are now so rare, that West's classical description of the final condition of such patients is seldom verified. Thanks to the increased intelligence of the profession, even the more obscure pelvic affections (ovarian and tubal) are often detected and submitted to surgical treatment, thereby saving many women from years of unnecessary suffering. It would seem strange that when the importance of laceration of the cervix is so widely acknowledged and the lesion is readily diagnosticated, its most serious consequence should be overlooked. Yet there is some excuse for this. So indefinite are the symptoms of commencing epithelioma, and so often are they masked by those referable to coexisting conditions, that specialist and general practitioner are alike deceived. Nothing is more natural or laudable than the desire on the part of the family physician to allay the fears of a patient who suspects the existence of cancer; but, unfortunately, this often leads him to defer the examination until it is too late. The patient herself is then the first to blame him for not insisting upon a measure to which she opposed so many obstacles. Specialists often fail to take into account the difficulties which are encountered by the attendant under these circumstances.

I propose to discuss this subject from a strictly practical standpoint, and shall touch lightly upon facts which are of more interest to the pathologist than to the clinical observer. It would be profitless to dwell upon the relative frequency of the different varieties of cancer of the cervix. I am in accord with Lusk (*American System of Gynecology*, vol. ii. page 602), who says:

> "The old familiar division of uterine cancer into scirrhus, medullary cancer, colloid cancer, and epithelioma at the present time has ceased to be tenable. It was based on tactile impressions, physical appearances, and peculiarities of growth. It represented not distinct varieties, but accidental conditions, or successive stages of development. It served to introduce into the subject an element of confusion detrimental to progress, as rarely two observers were found in agreement as to the classification of the disease in the same patient."

There are certain popular fallacies with regard to malignant disease of the uterus, which even yet exercise great influence over the medical mind. I allude more particularly to the importance assigned to the age and so-called "cachexia" of the patient, to hemorrhage, and to the presence of foul discharges from the vagina. Any one who has observed a number of cases of advanced carcinoma of the cervix must have been struck with the large proportion in which some, or even all, of these supposed pathognomonic symptoms are conspicuous by their absence. In over twenty per cent. of the recorded cases the patients are under forty years of age. Within the last year I have seen two women of twenty-four die from a recurrence of the disease, one after amputation of

[1] Read before the New York State Medical Society, February 5, 1889.

the cervix and the other after vaginal hysterectomy. Several women have come to my office with advanced epithelioma of two years' standing, who exhibited but slight evidence of ill-health; one of them has actually gained in weight since I amputated her cervix fourteen months ago.

Many, in fact the majority, of the patients at the Cancer Hospital are singularly free from pain. Pain, when it occurs, is a later symptom, referable to peritonitis rather than to the disease itself. Flooding, sufficient to jeopardize the life of the patient, is exceptional, in my experience. I am inclined to regard it as quite as rare as fatal hæmoptysis. The profuse, foul, watery discharge with which we are so familiar, is by no means a constant attendant of advanced malignant disease, even when extensive ulceration is present; careful observation of patients in hospital and private practice has frequently demonstrated to my satisfaction the fact that it may be slight, even in cases in which a vesico-vaginal fistula has formed. Of course, some allowance must be made for the effect of frequent vaginal injections (especially when the admirable deodorizer creolin is employed), but the cases to which I refer were those of patients who had recently come under observation and had not used any means to secure thorough cleanliness.

These prefatory statements with regard to the negative evidences of advanced malignant disease of the cervix, which are all based on careful records, will serve to show how slight may be the symptoms which attend the same disease in its incipient stage.

"The first symptom in five-sixths of all cases of cervical cancer," says Winckel, "is hemorrhage." Let us not understand by this profuse loss of blood, such as sometimes occurs during the stage of ulceration. The hemorrhage, which is only an expression of the local hyperæmia, may take the form of menorrhagia or metrorrhagia (more commonly the former) and presents different features according as it occurs in patients before, during, or after the climacteric. It has seemed to me in several instances, where the women were under forty, that the menorrhagia, from which alone they sought relief, was directly due to hyperplastic endometritis, and not to the condition of the cervix at all. In two recent cases I did not even suspect commencing epithelioma, but proceeded to curette the uterus and to excise the cervix, as in any case of bilateral laceration with extensive erosion and induration. A large quantity of fungosities was removed, and the hemorrhage was entirely relieved, the subsequent periods being normal. On microscopical examination of both cervices, there was no doubt as to the presence of malignant disease. Now, in these cases the hemorrhage was clearly due to the diseased condition of the endometrium, which doubtless preceded the development of epithelioma, being only a link in the pathological chain of which the first was the cervical laceration. I mention this point in order to caution the unwary against the error of inferring that because they have removed the immediate cause of the menorrhagia, nothing more remains to be investigated.

In these young women, I would lay particular stress upon one symptom, which is apparently so unimportant that it often passes unnoticed; I allude to slight hemorrhage (often a mere "show") after coitus. Most of the books mention this, but few emphasize its importance. If you take the trouble to question patients about this sign, you will be surprised to find how often it can be identified as the initial objective symptom of malignant disease. I need not enter into an explanation of its cause. Women of the better class will of course rarely mention it unless questioned, but I hold that it is the physician's duty to inform himself on this point whenever he has the slightest suspicion of a sinister condition. Less often the same bloody discharge is noticed on straining during defecation. This single symptom, hemorrhage after coitus, led me to examine and to detect cancer of the cervix in a robust German woman, who had never had a single pain referable to the pelvic organs.

Irregularity in the recurrence and variation in the normal amount of the menstrual flow, are regarded by both the laity and profession as indicative of the approaching menopause. Börner, who has written the most recent monograph on this subject, lays great stress upon the fact that these "atypical" hemorrhages are frequently pathological in their character, the increased flow being really due to some morbid condition of the uterus. The patient is lulled into a sense of security, not only by her own feeling that her symptoms are due to the change of life, but by the assurance of her physician, who too easily concurs with her opinion and thinks that an examination is unnecessary. How often are gynecologists called to see women with fibroid tumors, who have been allowed to bleed for months until they have become almost exsanguinated, while they have been treated "expectantly," with the idea that hemorrhage was physiological and would cease spontaneously! Cancer of the cervix, of course, does not give rise to such profuse menorrhagia, but it causes an increase in the menstrual flow too marked to be referred to the climacteric alone. Even a bare suspicion that the condition is hyperphysiological should lead us to investigate thoroughly, since we know that malignant disease of the portio develops in the majority of cases in the fifth decade. The advice given by Hart and Barbour is sound, viz.: "In all cases in which a patient over forty years of age seeks advice with symptoms referable to the pelvis, a careful examination should be made."

There are certain peculiarities with regard to the

establishment of the menopause which should especially awaken our suspicions. Premature climacteric hemorrhages (between thirty-five and forty) are usually pathological; of still more doubtful import is menorrhagia prolonged after the age of fifty.

Börner goes so far as to state that in such women "the most perfect regularity in the monthly flow does not justify us in deciding at once that the conditions are normal, and that there is simply a delayed menopause."

Post-climacteric hemorrhages, it is hardly necessary to add, are a sinister omen. If they occur soon after the establishment of the menopause, both patient and physician may fall into the error of regarding them as simply a recurrence of the former menorrhagia; but, these hemorrhages are usually slight and insignificant, appearing at irregular intervals. There may be simply a pinkish discharge, which bears no resemblance to the atypical bleeding. Women are more likely to notice this symptom now than they were in earlier life, because they are always on the lookout for cancer after the "change." But, in spite of this, experience shows that even in such cases the existence of malignant disease is not recognized as promptly as it should be.

Pain in commencing epithelioma, as I have before stated, is seldom of such a nature as to afford a clew to the condition present. It seems to me an error to refer to any particular variety of pain as pathognomonic of malignant disease of the uterus. In the earlier stage the patient may have only an occasional vague, shooting pain in the back or in the lower part of the abdomen; or it may be of a dull, aching character. It should be remembered that she has already an extensive laceration of the cervix of long standing, and probably the remains of former peri-uterine inflammation, the symptoms of which would mask any fresh ones produced by the incipient cancer. I have noted that pain in the left sciatic nerve was the first symptom of beginning trouble in a patient in whom there was absoluteiy no indication of pelvic disease. The neuralgia was peculiarly intractable and had been treated for some time before she came under my care. It ceased immediately after amputation of the cervix and has never returned. Since my attention was called to this symptom I have observed it in other cases.

The characteristic watery discharge is not observed until ulceration occurs. But profuse leucorrhœa (without odor) is a common accompaniment of cervical erosions. When it is frequently streaked or tinged with blood, it becomes significant.

These symptoms, slight as they are, are all which have been noted in connection with incipient malignant disease of the cervix. They are so indefinite, that unless we are in the habit of regarding every pelvic trouble as serious until it is proved to be otherwise, we shall frequently either overlook them entirely, or regard them as not sufficiently important to justify an examination. Hebra used to say: "Any one can have syphilis." We might add: "Any woman may have cancer."

Supposing we are led to make a vaginal examination, are the feel and appearance of the cervix sufficiently characteristic to clear up all doubt regarding the diagnosis? I cannot answer unhesitatingly in the affirmative. The examining finger encounters a large indurated cervix, presenting a unilateral (or, more commonly, a bilateral) laceration, with eversion of the lips. The soft, velvety sensation imparted by the erosion may be masked by the general induration, which, it is important to note, is not confined to the angle of the tear. The everted mucous surface bleeds more readily than a simple erosion. Instead of the ovula Nabothi usually felt. small, hard nodules are often present. Spiegelberg's test—immobility of the mucous membrane over the subjacent indurated tissue—is of no practical value. I would rely principally on the general sclerosis of the hypertrophied cervix, associated with bleeding of the everted mucous membrane. The uterus is usually enlarged, but this enlargement is of long standing, resulting from the original laceration; it is, as a rule, movable at this stage. The cervix is often quite insensitive, although tenderness is more likely to be present than after ulceration has occurred. Inspection of the diseased parts through the speculum adds but little to the information obtained by the touch. The examiner sees a hypertrophied cervix with an angry-looking erosion. According to Stratz (*Zeitschrift für Geb. u. Gyn.*, Bd. xiii. Heft 1), a sharp line of separation between the diseased and healthy tissue will be observed, the former occupying a somewhat higher level. Scattered through the latter will be seen glistening, yellowish-white nodules, which on section present a granular appearance. It is safe to say that these are not constantly present; they are rather a manifestation of that form of carcinoma which begins as nodules beneath the mucous membrane. Schroeder believes that every papillary growth on the cervix having a broad base, should be regarded as cancerous; on the other hand, if a papillary ulcer is surrounded by a zone of follicles it is more likely to be benignant.

The text-books instruct us in case of doubt to excise a piece from the cervix and to submit it to microscopical examination. This is excellent advice, which certainly should be followed in every instance where the decision of the surgeon with regard to the performance of a radical operation is based entirely upon the pathologist's report. I would have had less cause for regret if I had not omitted to take this precaution on one occasion. But the pathologist sometimes rightly declines to shoulder all the responsibility. The microscopical appearances

of the suspected tsisue are such that he does not feel justified in giving a positive opinion with regard to its malignancy. With Virchow's experience fresh in our minds, we cannot afford to blame any microscopist for sometimes hesitating. I have dilated on this subject in a recent paper on "The Microscopical *versus* the Clinical Evidences of Malignant Disease" (*N. Y. Medical Journal*, June 18, 1887), in which I called attention to the fact that it was sometimes necessary to examine many sections of suspected tissue before one was found which justified the pathologist in making the diagnosis of cancer, and that the small fragment submitted for examination might not be taken from the most characteristic portion of the cervix. In short, the evidence afforded by the microscopical examination may be entirely negative.

In excising a fragment for examination, be careful to take out a generous wedge, including both the mucous membrane and the subjacent muscular tissue. The pain is insignificant, so that I never use an anæsthetic. Select the most suspicious spot, seize the underlying tissue with a tenaculum, and remove the wedge with two snips of the scissors. I shall not enter upon a description of the microscopical appearances in simple erosion and in epithelioma, but shall merely call attention to the main point which should be considered in deciding upon the character of the suspected tissue. It is not enough, as Friedländer clearly shows, to apply Waldeyer's definition of cancer—"an atypical proliferation of epithelium"—since the same atypical cell-processes may be seen in sections of a simple erosion. Evidence of active cell-proliferation, granulation tissue, glandular hyperplasia—all these may accompany a purely benignant condition. The malignancy of the process is shown by its disposition to invade the deep-lying parts, while an innocent growth remains limited to the tissue from which it originated. Friedländer expresses this so clearly that I quote the following from his work on "Microscopical Technology": "If we discover in the uterus that the process is not confined to the mucous membrane, but that it also invades the muscular tissue, and that the muscle is partly replaced by granulation tissue traversed by outgrowths of atypical epithelium, we have to do with a clearly malignant element, and then only do we make the positive diagnosis of cancer." It will be evident from this that you cannot blame the pathologist if he refuses to give you a positive opinion unless you send him something more than a mere snipping from the hypertrophied mucous membrane.

There should be little room for doubt regarding the proper treatment of these cases, whether cancer has actually developed or not. In every case of laceration of the cervix, accompanied by extensive erosion and induration of the subjacent tissues, the proper course to pursue is to excise all the diseased tissue, even if this involves ablation of the entire cervix. This is only following Emmet's teaching in regard to the thorough excision of the "cicatricial plug." "I have always," he states, "advocated and practised removal of the cervix where the tissues have become so degenerated that the fear of epithelioma might be entertained. The occasion is rare, but recently I have resorted to the operation in several instances as a precaution, from witnessing epithelioma spring up in a case in which I had trusted too much to the reparative power." It seems to me that "excision" is a more correct designation for the operation than "amputation;" the latter is more properly applied to removal of the cervix in cases of actual elongation or hypertrophy. Excision, as I understand it, is by no means so rarely indicated as one would infer from the above quotation, and it would be well if it were practised more frequently instead of simple repair of the existing laceration. The same rule applies here as in any operation for the removal of neoplasms in general surgery—amputation of the breast, for example—to excise freely all suspicious indurated tissue bordering on the original wound.

It is unnecessary to dwell upon the technique of excision, which is somewhat similar to that of Schroeder's operation for the radical cure of cervical endometritis, the vaginal mucous membrane being preserved in both instances, although in the former much more of the cervical tissue is removed. The introduction of a plug (of iodoform-gauze or glass), in order to keep the canal patent, is an important point, nor should it be forgotten that the sutures must be inserted more deeply than usual if the surgeon would insure union of the underlying parts. Silver wire can alone be depended upon in these cases. The inexperienced operator must be neither too timid nor too bold, since he will, on the one hand, not remove all the diseased tissue, or, on the other, he will enter the subperitoneal space—an accident which may lead to unpleasant consequences if the operation is not thoroughly aseptic. The latter will be avoided by always cutting toward the centre. If this caution is followed, the apex of the cone may be as high as the os internum, the mucous lining of the entire cervical canal being removed with the cone. Remembering the insidious manner in which cancer originates in, and creeps along, the cervical endometrium, it will be apparent that an attempt to preserve a strip of undenuded tissue in the canal will probably defeat the object of the operation, which is to remove all the diseased portion of the cervix, and thus to provide against future recurrence.

The fear of hemorrhage during operations on the cervix is incomprehensible to those who have had much experience in minor gynecological surgery.

The "circular artery" is a veritable bugbear. Out of five or six hundred operations which I have observed, I cannot recall one in which the bleeding was not promptly and effectually controlled by a single deep suture. It may be asked: "Can excision be properly performed by the general practitioner?" Why not, providing that he is competent to repair a laceration of the cervix? It is important to note, however, that one must be able to deal with every complication that arises, the same as the would-be laparotomist. It is certainly unfortunate for a tyro to subject a woman to a laparotomy which is not completed simply through his timidity or lack of experience; on the same principle, the general practitioner, whose experience is necessarily limited, may shrink from excising the entire cervix when necessary, confining himself to a partial operation which is worse than useless. It is better to allow to heal by granulation rather than to obtain perfect union at the expense of leaving behind a focus of malignant disease.

A word with reference to the ultimate results of excision. I would not be understood as urging it as a substitute for a more radical operation, when the latter is clearly indicated, but I do regard it as the only justifiable measure when the cervix is only "suspicious." A sufficient number of cases of vaginal hysterectomy (some of which terminated fatally) for simple erosion of the cervix are on record to render us somewhat cautious about resorting to this radical treatment until the disease has developed beyond the shadow of a doubt.

Excision is a simple, safe, and effective operation, unattended by subsequent complications, which often nips the disease in the bud, so that it never returns. Even if it does, the recurrence is promptly observed, and high amputation or vaginal extirpation may then be performed just as well as at first. Another consideration, by no means unimportant, is the fact that by performing the minor operation we spare the patient the thought that her condition must be wellnigh hopeless in order to call for removal of the entire uterus. The dreaded word "cancer" need not be mentioned, neither is it necessary to impress her with our own gloomy forebodings. It is enough to explain to her that her condition is such that the prompt performance of a minor operation will save her serious trouble in the future. By the exercise of a little tact, she may be spared the knowledge of how narrowly she escaped that danger, as well as the agonizing doubt of patients who live in constant dread of a recurrence of the disease.

Summary.—The majority of the cases of cancer of the cervix uteri do not come under the observation of the surgeon before the disease has progressed so far that it is impossible to perform a *successful* radical operation. The attending physician is too often responsible for this delay, although he is not entirely inexcusable for misinterpreting the initial symptoms.

The symptoms of incipient malignant disease of the cervix are seldom characteristic, but they are such as to awaken suspicion and to justify an examination. Slight, irregular hemorrhages, especially after coitus, are always significant, above all in women who have passed the menopause. Pain is seldom characteristic. There is no offensive discharge in the early stage.

Hypertrophy and general induration of the cervix, accompanying an erosion which bleeds easily to the touch, should lead the physician to confirm the diagnosis by excising a fragment of the suspected tissue and subinitting it to microscopical examination.

A positive opinion regarding the presence of malignant disease is justified only by the finding of processes of atypical epithelium which *invade the subjacent muscular tissue.*

Excision of the cervix should be performed in every case of extensive erosion with general induration, whether cancer has actually developed or not. This is often sufficient to insure a cure, and thus to render a radical operation unnecessary. If the disease recurs, the uterus may be extirpated subsequently.

OBSERVATIONS ON THE DIGESTIVE FERMENTS.[1]

BY R. H. CHITTENDEN, PH.D.,
PROFESSOR OF PHYSIOLOGICAL CHEMISTRY IN YALE UNIVERSITY.

RECENT years have witnessed a marked development in our knowledge of the physiology of digestion. A great mass of histological and physiological details has been gradually accumulated by which a clearer insight has been obtained into many of the processes of secretion, digestion, and absorption. Chemical science has lent its aid and given us light on the composition and character of the digestive juices and on many hitherto obscure points in the metamorphism of the various food-stuffs, and at the same time taught us to appreciate its value in the study of scientific medicine.

There is, I think, no branch of medicine in which a proper appreciation and true understanding of physiological processes are so necessary as in the pathology of digestion. In the words of Dr. Ewald, "digestion is comparable to a complicated clockwork, the derangements of which are readily shown by the movements of the hands, but the causes of which are difficult to discover from the complexity and concealed position of the movement. Therefore, the

[1] Read before the Section on Pædiatrics of the New York Academy of Medicine, January 23, 1889.

pathology of digestion requires a well-grounded knowledge of the complex processes which effect the transformation of our food into chyle."

Among the more recently acquired facts pertaining to digestion, none are of more importance than those which relate to the digestive ferments. In the processes going on in the alimentary canal, by which the nutritive portions of the food are transformed into soluble and diffusible products fitted for the nourishment of the blood and of the tissues, ferments play an all-important part; without the action of the unorganized ferments, the nutrition and life of the organism would be impossible. As you well know, the more important digestive ferments or enzymes are of two kinds: amylolytic, acting on starchy matter, and proteolytic, acting on the albuminous food-stuffs. As examples of the former, we have the ptyalin of saliva and the amylopsin of pancreatic juice, as well as the diastatic ferment of the bile; as examples of the latter, the pepsin of the gastric juice and the trypsin or pancreatin of the pancreatic fluid.

The terms fermentation and ferment may be variously defined, but yet, after all, we cannot add much to the definition current in the fourteenth century, viz.: "a force which without becoming weaker itself can produce great effects in other masses." We know that this is not strictly correct, yet the amount of ferment involved in any given fermentation is, as a rule, so infinitesimally small, so out of proportion to the magnitude of the chemical processes or changes caused by it, and at the same time so continuous in its action, that we may well marvel at its power and wonder at its methods. We feign knowledge, however, and call it a *catalytic* action, a term which clearly exposes our ignorance but which helps to foster our self-esteem.

The amylolytic and proteolytic ferments are alike in that they act only in the presence of water; that the products of their action contain, as a rule, more oxygen and hydrogen than the original matter, thus implying a hydration process; and that their action is most energetic at the body temperature. They differ, however, in the medium in which they act: the amylolytic ferments being most energetic in a neutral fluid, wholly inactive in the presence of free acid; the proteolytic ferment pepsin, on the other hand, acting only when in combination with an acid, preferably hydrochloric, while trypsin acts best in an alkaline medium, although also active in a neutral fluid. These, what may be called minor points of difference are essential ones, however, and serve important purposes in the economy. For, the ferments are extremely sensitive to the action of foreign matters and the simple changes of reaction from acid to alkaline, and *vice versa*, met with in the alimentary tract are sufficient to destroy the different ferments as they are exposed to the changed conditions in their journey onward, and doubtless only such escape destruction as are absorbed and ultimately excreted through the kidneys. Thus, as we shall see, the amylolytic ferment secreted by the salivary glands is undoubtedly destroyed by the acid of the gastric juice, the proteolytic and rennet ferments secreted by the gastric glands are destroyed by the conjoined action of trypsin and the alkaline salts of the pancreatic and intestinal secretions, while the ferments of the pancreatic juice are probably in turn destroyed, at least in great part, by the acids of the large intestine.

Bearing in mind the extreme importance to the economy of these unorganized ferments, it may not be amiss to consider briefly some of the conditions which modify their activity. I am aware, however, that I am dealing with a much-abused subject, one possibly worn threadbare, certainly one concerning which of late years much has been said and written. But there are many conflicting statements, many downright contradictions, and I have ventured out of my experience in the laboratory to present to you the results of my own observations, enlarged somewhat by those of others which have seemed to me worthy of credence. A somewhat continuous study of the digestive ferments in their relation to normal digestive action has led to an accumulation of data,[1] most of which, to be sure, have come from bottle and test-tube study, but yet I think not to be ignored on that ground, nor on the other hand to be accepted necessarily in their entirety, but to be looked upon as statements of fact so far as they go, and as suggestions to be tested clinically when of sufficient importance. So far as the pure chemistry of digestion is concerned, the nature of the ferments and their action, the influence of various agents on their activity, etc., the laboratory is the proper place for such study and the data so obtained may be of great advantage in pointing the way for clinical experiments. It is to be ever borne in mind, however, that the living alimentary tract is a somewhat different mechanism from a glass beaker and that in the former we have to deal with a complication of conditions not met with in our artificial digestions.

In considering first the action of the amylolytic ferments, we will speak only of the ptyalin of saliva and the diastase of malt; the one as an illustration of a normal digestive ferment, the other as a good example of a common remedial agent.

What is true, however, of the ptyalin of saliva is also applicable to the amylolytic ferment of the pancreatic fluid.

Human mixed saliva as ordinarily secreted has an alkaline reaction, the average of fifty-one samples

[1] See Studies from the Laboratory of Physiological Chemistry. Sheffield Scientific School of Yale University. Vols. i.–iii.

showing an alkalinity equal to 0.08 per cent. sodium carbonate. The highest amount found was 0.144 per cent., the lowest 0.059 per cent. In spite of this being the normal reaction of the secretion, its power of digesting starch is far greater when the fluid is exactly neutral than when alkaline, a difference which shows still more distinctly the greater the fluid is diluted. The ferment acts most energetically in a neutral fluid. The same is true of the diastase of malt, its diastatic action showing stronger in a neutral fluid than in an alkaline medium. Increasing the alkalinity of the fluid, either diastase or saliva, tends to retard the amylolytic action of the ferment, the extent of retardation being in proportion to the amount of alkali carbonate present. The percentage of alkali, however, which hinders diastatic action can be designated only for definite mixtures, being dependent upon the dilution of the fluid and consequently upon the amount of albuminous matters and inorganic salts present. The presence of 0.3–0 5 per cent. sodium carbonate will almost entirely stop the action of undiluted saliva on starch, while with neutral saliva greatly diluted the presence of even 0.005 per cent. sodium carbonate will diminish decidedly the action of the ferment. Dilute alkalies not only hinder the action of these amylolytic ferments, but they also destroy them, especially at the body temperature. Their destructive power, however, is not as great as their retarding action. While these facts plainly indicate the extreme sensitiveness of the ferments toward alkaline fluids, we must not be too hasty in assuming a destructive action whenever alkalinity becomes pronounced. Peptones and proteid matters, in general, all tend to diminish and even prevent in part the retarding and destructive action of dilute alkalies, hence in the intestinal canal and elsewhere where the products of proteolytic action or other forms of proteid matter are present, the amylolytic ferments may endure the presence of amounts of alkalies which alone would quickly lead to their destruction.

Toward acids, the amylolytic ferments, both ptyalin and diastase, are more sensitive even than toward alkalies. When diluted, neutral saliva or a solution of diastase is mixed with diluted hydrochloric acid in such proportion that the mixture contains only 0.003 per cent. of the free mineral acid, amylolytic action is stopped almost completely. With 0.005 per cent. of free hydrochloric acid destruction of the ferment is complete in a very short time, especially at the body temperature.

It has been generally held hitherto, and is even now to some extent, that the ferments of saliva and diastase as well regain their power of transforming starch into sugar when they reach the small intestine, where the contents are alkaline, this view assuming that in the stomach the activity of these ferments is simply suspended by the acidity of the gastric juice. It has even been questioned whether the acidity of the stomach contents ever becomes sufficiently great to stop completely the solvent action of the amylolytic ferments on starch.

Many eminent authorities stand committed to this view of non-destruction by the gastric juice, but it is a question easily settled by experiment, and I am quite convinced that the presence of a few thousandths of one per cent. of *free* hydrochloric acid is sufficient to stop quickly all amylolytic action. We are to bear in mind, however, that because a fluid reacts acid to test-papers, it does not necessarily follow that it contains free acid. In gastric juice, for example, especially after digestion is well under way, there are present comparatively large amounts of albumoses, peptones, etc., all of which unite with the acid of the gastric juice, forming a *loose* chemical combination, to be sure, but yet one in which the acid is far less powerful toward ferments at least than when uncombined.

Hence the question of retardation and destruction of amylolytic ferments in the stomach needs further consideration; we need to know how the presence of proteid matter affects the action of the acid of the gastric juice, and we find, by experiment, that nearly all forms of albuminous matter prevent, to a certain extent, the destructive action of the acid. The acid-proteids formed, however, have more or less of a destructive action themselves, and when all the proteid matter present in a given mixture is completely saturated with acid, although no free acid may be present, the amylolytic ferments soon lose their action on starch, and in a short time are completely destroyed. Hence it follows that while the proteids of the food probably protect for a time the ptyalin of the saliva, or other amylolytic ferments introduced, by combining with the hydrochloric acid as it is secreted, in a very short time these must become saturated, and free acid be present; and as soon as free hydrochloric acid is present, or even before, a rapid destruction of the amylolytic ferments must take place. And to this destructive action must be added, also, the slower action of the acid-proteids. That free acid is normally present in the stomach contents can be easily shown by several tests, notably with tropæolin oo. The length of time after the ingestion of food, before free acid makes its appearance in the stomach must be variable, dependent in great part upon the amount and character of the food taken.

There is, I think, among many physiologists a growing impression that for fifteen to thirty minutes after taking food an active digestion of starch goes on in the stomach. Von Velden[1] found, by methods perhaps somewhat questionable, that for a time vary-

[1] Zeitschrift für physiologische chemie, 3, p. 205.

ing from three-quarters of an hour to two hours after eating, the fluid in the stomach, obtained by a stomach-pump, gave no color reaction with methyl-aniline violet or tropæolin for free acid, although the mixture showed an acid reaction to test-papers. Uffelmann,[1] likewise, found a similar absence of free hydrochloric acid in the case of a boy with a gastric fistula, and fed on a mixed diet, free acid appearing from forty-five to sixty minutes after the ingestion of food. Kretschy and Seemann obtained similar results. More recent experiments of Ewald,[2] however, appear to show that the time of appearance of free acid depends entirely on the food; thus, in one experiment, with a person where vomiting could be produced at will, a meal of sixty grammes of wheat bread was followed by the appearance of free hydrochloric acid in the stomach contents in thirty minutes; with hard-boiled eggs, even after fifteen minutes. With a moderate meat diet (120 grammes) free hydrochloric acid was detected only after one and a half hours. Further, Ewald and Boas,[3] by experiments on inmates of the "Städtischen Frauen-Siechen-Anstalt," Berlin, have found that on feeding starch-paste (200–300 c.c.), made from either potato or wheat starch, free hydrochloric acid appears in the stomach contents very quickly. The experiments were conducted on patients with sound stomachs, the stomach being empty, and indeed rinsed out with water just prior to the experiment, and the wash-water proved free from acid. In this way they found that the ingestion of the starch-paste was followed in one case by the appearance of free hydrochloric acid in ten minutes, the fluid vomited containing 0.04 per cent. HCl, the acid increasing after twenty-seven minutes to 0.28 per cent. In another experiment, after the same order, 0.13 per cent. HCl was found in the fluid ejected after fifteen minutes, while at the end of thirty minutes the acid had increased to 0.29 per cent. In no case was lactic acid found in the ejected matter.

These same investigators have also, in part, confirmed our statements regarding the action of acids on the amylolytic ferment of saliva, by a series of interesting clinical experiments on patients in the Frauen-Siechen-Anstalt. By feeding a one per cent. starch-paste solution to which a definite amount of hydrochloric or other acid had been added, to patients whose stomachs had been previously rinsed with water, they found that the smallest percentage of hydrochloric acid which would hinder the formation of reducing substances was 0.066 per cent., the stomach contents being ejected or withdrawn five to forty-five minutes after the ingestion of the starch. With some patients, however, the acid could be raised to 0.1 or even to 0.12 per cent., and still have a trace of reducing bodies formed, the latter being presumably sugar. With lactic acid, the amount could be raised to between 0.1 and 0.2 per cent. and still have some starch converted. With butyric acid, 0.2 per cent. allowed some conversion. It must be remembered, however, that these percentages are simply the percentages of acid in the starch-mixture introduced into the stomach, and not the percentages of acid in the stomach contents, where there would naturally occur a dilution and partial neutralization from the inflow of alkaline saliva, counterbalanced, perhaps, by the secretion of acid gastric juice.

The most important point in this connection, however, is the fact that such conversion of starch as does occur in the stomach under these circumstances, takes place during the first five minutes, the amount of sugar found in the ejected fluid being the same at the end of five minutes as at twenty minutes; further, the amount formed is quite small, implying that the ferment is quickly stopped in its action by the acid present. Ewald also concludes that the presence of 0.077 per cent. of hydrochloric acid is sufficient, under the above circumstances, to destroy completely the ferment.

Coupling these facts with those already mentioned, I think we can safely conclude that the action of the diastatic ferments can, at the best, continue only for a short time in the stomach, and that cessation of amylolytic action is quickly followed by destruction of the ferment, through the action of the free and combined hydrochloric acid. Further, it is obvious that the administration of diastatic ferments, however active, by mouth, with the intention of supplementing the pancreatic digestion of starch in the small intestine, can be of little value, since the ferment must inevitably be destroyed before reaching the seat of action.

The extreme sensitiveness of the amylolytic ferments toward acids is substantiated by their behavior toward many common therapeutic agents;[1] many of the so-called antiseptics and germicides likewise show marked action on these ferments, even when present in very small quantities. Mercuric chloride or corrosive sublimate, also mercuric iodide and bromide retard the action of the amylolytic ferments, even when present in a few thousandths of one per cent. Curiously enough, mercuric cyanide, when present in small amounts, appears to increase the solvent action of these ferments on starch. Large percentages, however, retard their action. Sulphate of copper has a very marked inhibitory action, while lead acetate has a retarding action only when present to the extent of two or three per cent. Arsenious oxide and ammonium

[1] For the quantitative data, showing the exact amount of retardation or stimulation of amylolytic action, see vol. i. of Studies in Physiological Chemistry, Yale University.

arsenate, in small fractions of a per cent., both cause neutral saliva to convert a larger amount of starch into sugar than the saliva alone would do, while arsenic acid retards the action of the ferment. Tartar emetic, in small amounts, has a marked stimulating influence on the salivary ferment, but large amounts, as five per cent., very noticeably diminish the amount of sugar formed. Potassium chlorate, in small quantities, increases the amylolytic action of saliva, while the presence of even five per cent. of the salt has only a slight retarding effect. Sodium chloride, likewise, has a slight stimulating action, and large percentages cause only a slight diminution in the amount of starch dissolved. Many of the alkaloidal salts cause the salivary ferment to form an increased amount of sugar, apparently through stimulation of the ferment, notably morphine sulphate, quinine sulphate, cinchonine and cinchonidine sulphates, atropine sulphate, and brucine sulphate. Strychnine sulphate, on the other hand, has a slight retarding action on the ferment. Antipyrin and antifebrin both have a slight inhibitory action on the salivary ptyalin. Urethan, in small fractions of a per cent., has a slight stimulating action, while larger amounts diminish somewhat the quantity of sugar formed. Thallin sulphate, in very small percentages, has a noticeable stimulating action, while paraldehyde has a marked inhibitory effect.

Of gases, oxygen and carbonic acid both decidedly increase the amount of sugar formed by neutral saliva, while hydrogen noticeably diminishes the action of the ferment.

Pepsin, the best known of the proteolytic ferments, and perhaps the most important, has been the subject of study for many years. Ever since Eberle, in 1834, called attention to the solvent power of an acid extract of the stomach mucosa, investigators have been at work in a vain attempt to isolate the active principle in a pure state. Schwann named the hypothetical substance pepsin, and Wasmann, just fifty years ago, made an elaborate but fruitless attempt to isolate the pure ferment. Even at that time the powerful digestive properties of the ferment were recognized, for Wasmann states that a weak acid solution, containing only $\frac{1}{60000}$ part of the impure ferment, will dissolve coagulated albumen in from six to eight hours. A long row of illustrious names may be added to the list of those who have endeavored to widen our knowledge of this proteolytic ferment. Pappenheim, Valentin, Elsässer, Frerichs, C. Schmidt, and many others may be mentioned as among the first to work upon this subject, while nearly every prominent physiologist since has made some contribution to broaden our knowledge of this digestive ferment.

Among the many facts connected with the proteolytic action of pepsin, which it is important for us to remember, is that the acidity of the gastric juice is mainly due to free hydrochloric acid. The elaborate experiments of Bidder and Schmidt still stand the test of criticism, and while we have many times, especially in disordered conditions of the stomach, lactic, butyric, acetic, and possibly other acids present in the stomach contents, we are to look upon them as the products of various forms of fermentation, rather than as secretory products from the stomach cells.

Richet[1] has claimed that the hydrochloric acid of the gastric juice does not exist free, but in a state of loose combination with leucin, as chloride of leucin. His experiments are of value, since they furnish added proof that the gastric juice contains but one mineral acid; but few physiologists are inclined to believe that it exists combined with leucin. Certainly, for a vigorous gastric digestion, free acid is as indispensable as pepsin itself. Leucin is undoubtedly often present in natural gastric juice, and in extracts from the stomach mucosa, but I have many times also found considerable quantities of xanthin, hypoxanthin, and other similar crystalline extractives, and I see no reason for assuming a combination in the one case any more than in the other.

As to the strength of hydrochloric acid in the gastric juice, Richet, as the mean of seventy observations on a patient who had had gastrotomy performed for an impermeable stricture of the œsophagus, found 1.3–1.7 per mille. Other physiologists give somewhat higher results and 0.2 per cent. is usually taken as the average content of acid in active gastric juice. It can be easily shown, however, by experiment, that the strength of acid best fitted for digestion depends somewhat upon the amount of ferment present, and the character of the proteid to be digested. Using a pepsin extract of moderate strength and blood-fibrin as the proteid to be digested, we have found by quantitative trials that the most vigorous proteolytic action is usually obtained in the presence of 0.1 per cent. pure HCl. Thus, in one series of experiments where the amount of pepsin was the same throughout, with 0.05 per cent. HCl, 73.8 per cent. of the fibrin was dissolved; with 0.1 per cent. HCl, 89.3 per cent. of fibrin; with 0.2 per cent. HCl, 84 per cent of the fibrin; with 0.3 per cent. acid, 81.7 per cent.; while with 0.4 per cent. HCl only 63.8 per cent. of the fibrin was dissolved. It is also to be remembered, that while the proteolytic action of the ferment is most vigorous in the presence of hydrochloric acid, other acids will, to a greater or less extent, take its place, viz., phosphoric, nitric, sulphuric, oxalic, acetic, lactic, etc. Thus, with oxalic acid, proteolytic action is vigorous in the presence of 0.5–2 per cent. of the acid; most

[1] Du suc gastrique chez l'homme et les animaux.

vigorous with 1.5 per cent., such a mixture dissolving about three-fourths as much proteid as the same amount of pepsin with 0.1 per cent. hydrochloric acid. With nitric acid, proteolytic action is most energetic in the presence of 0.2 per cent.; with sulphuric acid, in the presence of 0.3 per cent. Compared with 0.1 per cent. hydrochloric acid, nitric acid is more than four-fifths as active, while sulphuric acid is little more than one-fourth as active, and acetic acid is practically worthless. Hydrobromic and hydriodic acids can, to a certain extent, replace the hydrochloric acid of the gastric juice, as Putzeys[1] has previously found, although they are both much less active than the latter. Moreover, hydrobromic acid is much more efficient than hydriodic acid in connection with the ferment, for in comparatively large doses the latter will completely stop all proteolytic action. Whenever bromides and iodides are taken into the stomach, they are supposed to be decomposed by the acid of the gastric juice, with formation of hydrobromic and hydriodic acids, respectively, by which the retarding action of these two salts on gastric digestion is produced. Hence, as a practical result, the bromides and iodides should be given one-half to one hour before meals.

There are, I presume, many diseased conditions where imperfect digestion is due as much to the want of necessary acid as to lack of ferment. Thus in fevers, as a rule from whatever cause, a less active gastric juice is secreted than normally, one possessed of far less proteolytic action, though generally acid. The acidity, however, is frequently diminished and, as Ewald remarks, confirms the old habit of prescribing phosphoric or hydrochloric acid in fever mixtures. The simple fact that the stomach contents are acid does not necessarily indicate that the fluid is of the proper degree of acidity or even contains the proper acid suited to the ferment. Acetic, lactic, or butyric acid may be present and render the stomach juices decidedly acid, and yet it be necessary to give acid in order to bring the acidity up to the point suitable for the best action of the pepsin.

It is also possible to give an acid, as possibly salicylic, which will have a double action, viz., an antifermentative one and a digestion-promoting one. Certainly in many forms of dyspepsia, as the researches of Ewald have shown, the derangement originates in the absence of the required degree of acidity rather than in insufficiency of pepsin. In many such cases there may be an "acid stomach" and yet the secretion of normal gastric juice be practically suppressed, the acidity being due mainly to lactic acid doubtless formed by fermentation in the stomach; an acid which acts with pepsin only about one-sixth or one-eighth as well as hydrochloric acid. Occasionally, as you know, the stomach contents have an alkaline reaction, as when a strongly alkaline transudation is poured into the stomach in connection with diminished or entirely abolished secretion of acid. Again, there are many other forms of dyspepsia or gastric troubles where there is a relative insufficiency of secretion, where pepsin as well as acid is wanting, and where artificial digestive preparations are especially called for.

With reference to the influence of drugs on the proteolytic action of pepsin-hydrochloric acid we have considerable definite information, partly as the result of experiments with artificial gastric juice and partly from observation on patients and animals with gastric fistula. Nearly all metallic salts diminish the proteolytic action of the ferment quite decidedly, even a few hundredths of a per cent. as a rule producing a noticeable effect. Thus cupric sulphate, lead acetate, mercuric chloride or corrosive sublimate, mercuric bromide, iodide and cyanide, salts of tin, zinc, manganese and iron, all have more or less of a retarding action on the digestive power of pepsin. Iron salts retard the action of the ferment much more than the corresponding salts of manganese. Mercurous chloride or calomel has been shown by Wassilieff to have no action whatever on the ferment. The action of these metallic salts is due, as a rule, to the combination of the metal with the proteid to be digested, forming an indigestible compound, and in part to a direct action on the ferment itself.

We have determined with all of these salts the exact amount of retardation or stimulation of peptic action under definite conditions, but I refrain from troubling you with the figures, especially as I think that the *extent* of action of a given amount of any drug in the stomach is, as a rule, greatly dependent upon the conditions, which are naturally variable, especially the strength of the pepsin-acid solution, the amount and character of the proteid to be digested, etc., and that it is better in applying these results to content ourselves with statements regarding the general nature of the action.

Arsenious acid has a noticeable stimulating or accelerating action on the ferment, the presence of even 0.5 per cent. of this substance causing the pepsin mixture to dissolve a much larger amount of albumen than the pepsin-acid alone will do. Arsenic acid has the same action, only still more pronounced, and the presence of even 2 per cent. of this compound leads to increased proteolytic action. This certainly accords with the generally accepted views as to the influence of arsenic on nutrition in general.

Potassium permanganate has a very energetic action on pepsin, the presence of even 0.005 per cent. in a digestive mixture reducing the action of the ferment to one-fourth the normal. Potassium cya-

[1] Jahresbericht der Thierchemie, 1877, p. 279.

nide and ferro-cyanide have marked inhibitory action on the ferment. Potassium chlorate and nitrate likewise retard the action of pepsin and when present to the extent of 1.5 per cent. both salts reduce the proteolytic action to one-fourth that of the normal ferment. Sodium tetraborate or borax and the chlorides of sodium, potassium, and ammonium all retard the digestive power of the ferment. Sodium chloride, in small amount, however, has a noticeable accelerating action. Potash and ammonium alum both retard digestive action. Sulphates of magnesia and soda likewise retard the action of pepsin, even 0.005 per cent. having a noticeable effect.

Nearly all of the alkaloid salts have more or less of a retarding action on pepsin; thus strychnine, brucine, veratrine, morphine, narcotine, quinine, cinchonine, and atropine sulphates all reduce the action of the ferment, morphine sulphate less than the others.

Bearing in mind that pepsin acts far less energetically with sulphuric and acetic acids than with nitric acid, and with the latter less actively than with hydrochloric, we can easily see that, as a rule, everything else being equal, sulphates will retard the digestive action of pepsin more than nitrates, and the latter more than chlorides, and if we are to apply such results as these to our practice it would be to use chlorides of the alkaloids, where practicable, rather than sulphates, and the same of inorganic salts. To be sure, after a short time, the alkaloid or its salts will have passed into the circulation and the stomach be freed from its influence, but it is well to heed the small things as well as the great, and if we can accomplish the same physiological effect with a chloride as with any other salt and thus avoid or lessen possible disturbance in the stomach it is perhaps as well to do so.

With alcohol we have a double effect to consider; the results of many experiments have shown plainly that the presence of alcohol impedes the proteolytic action of pepsin, even though it is present in comparatively small quantity; but as Gluzinski[1] has shown, alcohol rapidly disappears from the stomach, even 100 c.c. of 25 per cent. alcohol disappearing inside of fifteen minutes. While in the stomach, alcohol undoubtedly retards the solution of proteid matter. Schütz finds that 2 per cent. has a retarding action, while 10 per cent. causes a very great retardation, and 15 per cent. allows only a slight digestive action. Bikfalvi finds similar results, as do likewise Ogáta and Klikowicz. The disappearance of the alcohol, however, is followed by the secretion of an active, strongly acid gastric juice, which continues generally long after the food is entirely digested. Hence, under the influence of alcohol, there is often an accumulation of large quantities of fluid in the stomach, frequently colored yellow by bile. With small quantities of alcohol, therefore, especially with an abundance of food, there is an undoubted stimulation of proteolytic action induced mainly, if not wholly, by the increased secretion of hydrochloric acid. Under such circumstances the first stage of retardation is hardly to be considered, since the alcohol disappears so rapidly. With large amounts of alcohol, the mechanical functions of the stomach are interfered with, and thus the food compelled to remain a much longer time in the stomach than normally.

Beer, wine, and stronger spirits all have retarding action, according to the experiments of Ogáta[1] on a dog with gastric fistula. In the case of beer, Ogáta found that the retarding action was due equally to the alcohol contained in it and to the extractive matters. Even sugar, both grape-sugar and cane-sugar, when taken in quantities above 10 grammes, tends to retard the digestive action of pepsin, but on account of its rapid absorption such action is, of course, only temporary. Soda water, or carbonic acid water, in quantities of 200 c.c. or more, moderately strong infusions of tea and coffee, and 200 to 300 c.c. of spring water, were all found to have no appreciable influence on gastric digestion in the stomach itself.

Sodium salicylate,[2] in doses of from 2.5 to 5 grammes, has a marked retarding influence on the digestive action of pepsin. Chloral hydrate, according to Klikowicz, is without action on pepsin, in doses up to 1 gramme. With 2 to 3 grammes, however, there is noticeable retardation of digestive action, which, with larger doses, becomes still more pronounced.

Among the newer drugs, antipyrin and antifebrin both retard the action of pepsin; antipyrin, when present to the extent of 3 per cent., almost entirely stopping the action of the ferment. Paraldehyde has a very pronounced stimulating effect when present in small quantity, and even 2 per cent. has only a slightly retarding effect. Urethan has a very slight inhibitory effect, while thallin tends to increase the digestive action of pepsin.

In contact with dilute sodium carbonate pepsin is very quickly destroyed, especially at the body temperature. Experiments made with scale pepsin and pepsin extracts from the stomachs of various animals, have shown plainly that destruction invariably takes place in the presence of 0.05 per cent. of the alkali carbonate; hence, when the acidity of the gastric juice is neutralized in the small intestine, and the mixture becomes alkaline, there will be a rapid destruction of the pepsin, aided, as Langley has found, by the trypsin of the pancreatic fluid.

[1] Jahresbericht der Thierchemie, 1886, p. 263.

[1] Archiv f. Hygiene, iii. p. 204.

[2] Klikowicz: Jahresbericht der Thierchemie, 1885, p. 277.

Trypsin, the proteolytic ferment of the pancreatic juice, acts freely only in neutral or alkaline fluids, slowly and imperfectly in feebly acid fluids. Thus, in an experiment on fibrin, a neutral solution of trypsin digested 77 per cent. of the proteid, while the same amount of ferment in the presence of 0.4 per cent. sodium carbonate digested 96 per cent. in the same length of time, and in the presence of 0.1 salicylic acid only 44 per cent. of the proteid. Under ordinary circumstances the ferment appears to act most energetically in the presence of 0.5 per cent. sodium carbonate, but it will act even in the presence of 5 per cent. of the alkali salt. In no case will a salicylic acid solution act as vigorously as a neutral solution of the ferment. It appears, however, that in the acid-reacting fluid, the ferment simply acts more slowly, and if time be given, will ultimately approach the action of the neutral fluid. In such cases, however, the salicylic acid is not free, but combined with the proteid matter; free acids, either mineral or organic, even a few thousandths of a per cent., completely stop the proteolytic action of trypsin, and the addition of dilute hydrochloric acid to a neutral trypsin solution will prevent all proteolytic action, even before the proteid matter is completely saturated; after which the acid quickly causes the death of the ferment. A glycerin extract of the pancreas, for example, on being warmed at the body temperature, with even 0.05 per cent. hydrochloric acid, soon loses its proteolytic action; and, as Langley has shown, the presence of pepsin aids in the destruction. Hence, it is obvious that pancreatic extracts or ferments given by mouth can be of no value whatever, since the proteolytic ferment at least will undoubtedly be destroyed in the stomach before reaching its normal sphere of action.

It seems to me very desirable, however, to be able to use the pancreatic ferments as an aid to pancreatic digestion in the small intestine. The use of such preparations, however, even though fortified by doses of sodium carbonate or bicarbonate, can avail little, since destruction must inevitably follow their entrance into the stomach. I have seen, however, proclaimed somewhere a form of capsule insoluble in dilute acid, but soluble in alkaline fluids, which if truly possessed of such properties could be made an easy means of introducing both the amylolytic and proteolytic ferments into that portion of the alimentary tract where they are capable of performing their characteristic functions. Without some such method of protection it is of course useless to administer trypsin by mouth with any hope of gain to the economy.

As you doubtless know, the action of trypsin is peculiar in that there is no swelling of the proteid matter as in the action of pepsin and acid, but the albuminous substance is eaten into, crumbles, falls apart, and then dissolves. Further, the action of trypsin is peculiar in that it not only converts the albumen into peptone, but also decomposes a portion of the latter with formation of leucin, tyrosin and other products. With pancreatic digestion, the digestive function of the alimentary canal reaches its highest point, and, so far as proteolytic action is concerned, trypsin is undoubtedly more highly organized than its neighbor pepsin; the changes produced by it are more pronounced and deep-seated.

I would be glad to give you some idea of the relative activity of pepsin and trypsin as proteolytic ferments, but this I can hardly do with exactness. In normal digestion the two ferments work under such divergent conditions and the products of their action are so different, that it would perhaps be hardly correct to measure their relative action by the amount of albumen they are capable of dissolving. Again, so far as I am aware, attempts to obtain the pure ferments for pharmaceutical purposes have not as yet been as successful with trypsin as with pepsin. Looked at from the purely physiological standpoint, I am of the opinion, from my own experiments with the two ferments, that pure trypsin will prove to be more energetic in its action than pepsin, but the manufacturing chemists have yet to make a trypsin preparation equal in action to many of the brands of pepsin now in the market.

As a solvent of pseudo-membranes, as in diphtheria and in croup, the digestive ferments are certainly destined to prove of considerable value. Both pepsin and trypsin are recommended, but from a partial study of the various digestive ferments at present obtainable, I am inclined to consider pepsin as the most efficacious. If a trypsin preparation could be obtained in strength equal to many of the preparations of pepsin, I should be inclined to its use for the reason that it acts best in an alkaline medium, that it will eat into and disintegrate the fibrinous membrane rather than first cause it to swell up; that the alkaline secretions of the buccal and other glands will favor its action; that the alkaline fluids possible to introduce with the trypsin may have a slight solvent action in themselves on the diphtheritic membrane and that the ferment will act after the excess of alkali carbonate has disappeared.

These minor advantages, however, are, at present at least, far more than counterbalanced by the much greater activity of the ordinary pepsin preparations. Further, a large number of experiments to demonstrate the influence of various therapeutic agents on the proteolytic action of trypsin have shown me that, as a rule, this ferment is far more sensitive to the presence of foreign salts and drugs than pepsin is, and while this fact need not be considered here, yet it may influence us somewhat in favor of the latter ferment. Trypsin, however, is not much affected by the powerful oxidizing salt potassium chlorate, the presence of even five per cent. of this salt caus-

ing only a slight diminution in the solvent power of the ferment.

As we have seen, the solvent action of pepsin on proteid matter is most pronounced in the presence of 0.1–0.2 per cent. hydrochloric acid, but a thin solution of pepsin with this acid would very quickly rinse down when sprayed into the throat for the dissolving of pseudo-membranes. Admixture of glycerine will, in part, prevent this and keep the ferment for a longer time in contact with the surfaces to be dissolved. Obviously, the operation of painting or spraying must be frequently repeated, in order to keep the surface well moistened with the digestive fluid. Again, since pepsin will not act at all in a neutral or alkaline fluid, it is plainly better to have the digestive mixture at the outset contain at least 0.3–0.4 per cent. of actual hydrochloric acid. This will, in part, provide somewhat for the natural dilution of the acid, and also for the neutralizing action of the saliva and other fluids. Further, acid of this dilution is innocuous, and is a not unpleasant and cleansing mouth-wash. So long as the fibrinous tissue can be kept acid, the solvent power of the ferment will be exerted, and, in this connection, it is to be remembered that there exists a mutual attraction between the acid and the proteid matter of the membrane, by which the acid will be retained longer than by perfectly inert matter. It is to be remembered, however, that such dilute acid has a tendency to swell up proteid matter, and we can conceive of cases where such application might be deemed inexpedient.

The capability of pepsin for dissolving blood fibrin is very great, and at the body temperature its action is quite rapid, and hence one would expect that, under suitable conditions, the fibrinous portion of a diphtheritic membrane would be attacked with considerable rapidity.

The ferment solution, however, should be carefully brought to the body temperature prior to its introduction, and the ferment itself should be of the strongest kind, so as to favor immediate action. The widespread use of pepsin for this and other purposes has led to the manufacture of large numbers of preparations of this ferment, some of which, at least, are of doubtful quality. This fact has been impressed upon me many times in the laboratory, where, for various physiological purposes, commercial pepsin has been employed. Further, during the last six months I have made a comparative study of a number of the more prominent pepsins in the market, determining quantitatively their relative proteolytic action. The general use of pepsin as a remedial agent in gastric troubles may well make us solicitous as to the character and strength of the preparations at our disposal, but as a solvent for pseudo-membranes, where rapidity of action is of the utmost importance and the life of the patient hinges on the result, we should be doubly sure of the character of the ferment employed. The methods at present suggested by the different pharmacopœias for testing the digestive strength of pepsin or pepsin solutions are somewhat variable, both in respect to the strength of acid employed, and in the character and condition of the proteid matter to be dissolved, and it may also be questioned whether the standard adopted is sufficiently high.

Nearly all of the methods now in vogue, either for pharmaceutical or physiological purposes, are based upon the older methods of Bidder and Schmidt, Ebstein and Grützner, and Gruenhagen,[1] and shorn of their details, consist essentially in a determination of the amount of coagulated egg-albumen or blood fibrin which can be dissolved by the ferment in a given time, an excess of proteid matter being present, and the amount of albumen dissolved being taken as a measure of the proteolytic action.

Such a method does indeed show which mixture or pepsin has the stronger digestive action, but does not give a very correct idea of the *relative* proteolytic power, for while the conditions in such an experiment or series of experiments appear to be the same in each case, they are in reality often very unlike. For, as Thompson,[2] in a recent article on comparative pepsin-testing, has well said, the amount of albumen in each test may be the same, and also the volume of the fluid and the amount of apparent ferment, and yet, as soon as digestion commences, the weaker pepsins quickly have more surface of albumen or fibrin to work upon than the stronger, and therefore show better than they should. Again, all who are familiar with pepsin-testing can easily see that the condition of the proteid matter to be acted upon becomes a very important factor in such a test. Whether blood fibrin or hard-boiled egg, the fineness of its division, the completeness of its coagulation, the thoroughness with which it is kept suspended in the digestive fluid, all tend to exercise a very important influence on the final result, and are necessarily a source of frequent error.

Still again, the strength of acid recommended by several of the pharmacopœias is such as to be at least suggestive of the formation of considerable acid albumen, by which the apparent strength of the ferment is correspondingly increased. To obviate these difficulties, and, if possible, to insure more accurate results in pepsin-testing, I have devised the following method, based upon the fact that fluid egg-albumen is essentially of the same degree of digestibility as coagulated albumen,[3] and that the ability to form albumose and peptone is possibly a more accu-

[1] See Hermann's Handbuch der Physiologie, Band 5, 2d Theil, pp. 75–77.

[2] The Druggists' Bulletin, vol. ii. p. 261.

[3] Wawrinski, Hermann's Handbuch der Physiologie, Band v., 2d Theil, p. 83.

rate measure of proteolytic action than the power of simply dissolving coagulated proteids.

The albumen solution is prepared after the manner recommended by Schütz.[1] A quantity of the undiluted white of egg is freed from globulin by the addition of hydrochloric acid of specific gravity 1.12, 4.2 c.c. to 300 c.c. of albumen, shaken gently and after standing some hours filtered. The fluid will then be found to have lost its viscosity, and to be perfectly clear. The acid will likewise have neutralized the alkali carbonate present, and converted the phosphates into acid salts. The solution, however, will not contain any free acid. 10 c.c. contain approximately one gramme of dry albumen; the exact amount can be determined in a sample by coagulation. The solution can be kept for some days, and so used in a large number of experiments.

The testing is conducted as follows; 10 or 20 c.c. of the albumen solution are measured out with a pipette and introduced into a suitable receptacle, a definite volume of pepsin solution, say 50 c.c., previously prepared by dissolving a weighed amount of the pepsin[2] in 0.2 per cent. hydrochloric acid, is added, and enough more 0.2 per cent. acid to make the entire mixture 100 c.c. The fluids are then placed in a bath at 40° C., and allowed to remain there for five or six hours.[3] No stirring is needed, no attention of any kind, other than to keep the mixture at the proper temperature, and there is no possible error from variations in the mechanical condition of the proteid. At the end of the allotted time, the mixtures are heated to boiling and the acid neutralized by addition of the equivalent amount of sodium carbonate, best in approximately a one per cent. solution. The unaltered albumen, as acid albumen, is at once thrown down as a heavy flocculent precipitate, and while still hot it is at once collected on a dried, weighed filter, washed thoroughly with boiling water, and dried at 110° C. From this is easily calculated the amount of albumen converted into soluble products under the conditions of the experiment, from which in turn can be calculated the relative proteolytic action of the pepsin tested. The figures so obtained, if the conditions have been properly arranged, give a much closer approach to the true proteolytic power of a ferment than any similar method with solid proteids, but even this does not tell the whole truth. There is still felt the influence already mentioned of the relative excess of unchanged albumen in those digestions where the ferment action is weakest, and hence, after having used the above method as a preliminary test, it is necessary to have recourse to a modification of the principle made use of by Brücke[1] years ago, and recently recommended by Thompson, of using sufficient of each pepsin or pepsin solution to convert the *same percentage* of albumen into soluble products. In this way only, so far as I am aware, can the true proteolytic power of a pepsin or pepsin extract be determined.

After these methods I have tested the following brands of pepsin, obtaining as a preliminary result the following figures expressive of their relative proteolytic action.

The "pepsinum purum in lamellis" having the highest digestive power, is taken as the standard (100).

	Preliminary test of relative proteolytic action.
1. Parke, Davis & Co.'s pepsinum purum in lamellis	100
2. Fairchild's pepsin in scale	73
3. Scheffer's dry pepsin, concentrated	70
4. Jensen's crystal pepsin	56
5. Ford's pepsin in scales	54
6. North's pure pepsin	36
7. Boudault's pepsin	35
8. Royal Chemical Co.'s pure pepsin	27
9. Scheffer's saccharated pepsin	16
10. E. Merck's pepsin germ. pur. pulv.	11
11. Lehn & Fink's powdered pure pepsin	0

From these data, which are the average of many results, we might infer that Fairchild's pepsin, for example, contains three-fourths as much active ferment as the pepsinum purum of Parke, Davis & Co., and that Ford's and Jensen's pepsins contain approximately half as much true ferment as the pepsinum purum. Such a conclusion, however, would be fallacious, and to obtain the true measure of proteolytic action we must proceed further and determine next the relative amounts of the different preparations needed to produce a like result in each case. After this method we find, for example, that it requires about twice as much of Fairchild's and Scheffer's pepsin to form a given percentage of peptone as of the pepsinum purum, and that of Ford's and Jensen's preparations about three times as much, thus showing that the true difference in proteolytic power is considerably greater than the preliminary results alone indicate. As a final result, then, we may consider the true proteolytic power of the above ferments, compared with the one of highest digestive power, to be as follows:

	Relative, proteolytic action.
1. Parke, Davis & Co.'s pepsinum purum in lamellis	100
2. Fairchild's pepsin, in scales	52
3. Scheffer's dry pepsin, concentrated	48
4. Jensen's crystal pepsin	35
5. Ford's pepsin, in scales	32
6. North's pure pepsin	16
7. Boudault's pepsin	14
8. Royal Chemical Co.'s pure pepsin	9

[1] Zeitschrift für physiologische chemie, Band ix. p. 581.

[2] 50–500 milligrammes of the pepsin in 1 litre of the acid, according to its proteolytic power.

[3] The conditions to be so arranged as not to have more than 50–60 per cent. of the albumen, at the most, converted into soluble products.

[1] Vorlesungen über Physiologie, p. 303.

In considering these results it is to be borne in mind that the same brand of pepsin is liable to slight variations in digestive power, doubtless dependent, in part, upon the condition of the membranes from which it is prepared. Thus, in several instances I have found one or two of nearly the same digestive strength, changing their relative positions, notably Nos. 2 and 3 and Nos. 4 and 5.

As to the actual strength of these preparations, 1 milligramme of the strongest pepsin converted into soluble products 198 milligrammes of the pure dry albumen, which would be practically equal to 2000 parts of fluid egg-albumen.

THE USE OF BARIUM CHLORIDE IN HEART DISEASE.

BY H. A. HARE, M.D.,

DEMONSTRATOR OF THERAPEUTICS AND INSTRUCTOR IN PHYSICAL DIAGNOSIS IN THE MEDICAL DEPARTMENT, AND IN PHYSIOLOGY IN THE BIOLOGICAL DEPARTMENT OF THE UNIVERSITY OF PENNSYLVANIA.

ONE of the most recent and one of the best evidences of the value of the study of the action of drugs upon the lower animals is given us by this substance. It will be remembered that Brunton and Ringer, of London, and Kobert and Bary, of Dorpat, have, at various times, published during the last few years their studies concerning the effect of barium on the circulatory apparatus of the frog and dog, and that all of them are in accord in the statement that it slows the heart very greatly, steadies its rhythm, and, at the same time increases the volume of blood thrown out of the ventricle. They have also found that barium increases blood pressure, and Kobert has, by a series of careful experiments, concluded that it brings about this change by an action on the muscular coats of the bloodvessels.

If large doses are used in the lower animals, the heart suffers systolic arrest from over-stimulation, and the strongest irritation of the vagus nerves fails to relax the systolic contraction. Still more interesting is the statement that this failure of the vagi to inhibit the heart is not the result of paralysis of these nerves, but is simply due to the excess of cardiac contractile power. The slowing of the pulse is not due to inhibitory influence, but depends solely upon the stimulation of the heart muscle, although it would seem probable that the vasomotor stimulation, by increasing the arterial resistance, may be, at least, a factor in the reduction of the pulse-rate. At one time, in the dog after large doses there is a period of increase of pulse-rate which is asserted to be due to stimulation of the accelerator nerves.

With this brief statement of the influence of barium upon the normal animal I wish to detail the results which I have reached in the employment of this salt in cardiac disease in man, and I also desire to thank Dr. E. T. Bruen for the opportunity of testing its action in several interesting cases at the German Hospital and to record my obligation to Drs. Steltz and Shurtleff, the resident physicians, for their kindness in keeping a record of the cases.

The first case which I shall detail occurred in my own practice, and was as follows:

CASE I.—A. W., æt. six, girl, has had for some months marked dyspnœa at night and some shortness of breath during the day. She has a history of rheumatism of a mild type, and her maternal grandmother is virtually bedridden with the disease, which is, in her case, of a purely arthritic nature.

The child is fairly well developed for her age, but has the typical dilated nostril and rapid respiration of cardiac trouble. There is no cough. Examination shows a loud mitral systolic murmur which is quite faint over the apex and increases greatly in volume as the ear follows it to the left axilla, while at the angle of the left scapula the murmur is remarkably loud. There has been no dropsy at any time.

Although, so far as I am aware, barium has not been tried in cardiac disease in children I ordered half a drachm of a solution of the strength of one part of barium to 100 parts of water to be given three times a day. From the first, the condition of the child at night was markedly improved, the dyspnœa was much less and the sleep not so restless. The pulse, which had been at 130 per minute, now remained at 80 when quiet, or 100 after exercise, and the area of the thrill over the apex was much less diffused than before. One of the chief evidences of improvement was the absence of that peculiar whirring, tumbling sound, so characteristic of such cases, the murmurs becoming well separated from one another and having a much more definite character.

The continued use of the barium in this case for over two weeks has caused no untoward symptoms, and the child has steadily improved, notwithstanding an attack of mild bronchitis in the meantime.

CASE II.—A man, æt. about thirty-five, was admitted to the German Hospital, suffering from acute dilatation of the heart, the result of suddenly lifting a very heavy beer barrel. His pulse was weak and irregular, and he frequently suffered from attacks of pain closely resembling angina pectoris, with marked expression of anguish. The use of barium chloride in the dose of a teaspoonful of a one per cent. solution relieved him markedly, increased the volume and force of the pulse wave and slowed it to as low a rate as 60 or even 58 per minute.

CASE III. was a man of about fifty, with a double aortic regurgitant murmur, complicated by Bright's disease of a benign type, in so far as the renal signs were concerned. There was some pain over the region of the heart. Under the influence of the barium, in drachm dose of the standard solution, the pulse became much slower and far more forcible.

I offer the following sphygmographic tracing for the purpose of showing what an atypical pulse was brought about by the barium in this case.

While the sphygmograph is virtually useless for most purposes, aortic regurgitation is a lesion which it is generally quick to record.

TRACING 1.

Sphygmographic tracing showing absence of Corrigan pulse in a case of aortic regurgitant and obstructive murmur. Note the sharpness of the upstroke and the lack of sudden fall so commonly seen in such cases.[1]

So far as we were able to discover, the barium caused no renal disturbance and the man expressed himself as very much improved.

CASE IV.—A colored man, æt. about fifty, suffering from aortic regurgitation, producing a very loud murmur, was placed upon the dose always employed by me in these studies. The pulse rapidly became more full and strong, and the comfort of the man was considerably increased.

The following tracing, taken from Case IV., shows much the same characteristics as does Tracing 1, the upward stroke being equally sharp, while the prolongation of the pulse wave is seen to be particularly well marked.

TRACING 2.

CASE V.—Adult, male, with a well-marked mitral regurgitant murmur. The pulse rapidly became slower and the heat more rhythmical under barium chloride. Before the drug was used the morning pulse-rate ranged from 108 to 92, while after the first dose the pulse went down to 72, and remained between this point and 60, until he was discharged from the house.

CASES VI. and VII. consist of two men who suffered from marked weakening and diminution of the pulse wave, and of irregular and excitable heart respectively. In other words, no lesion could be discovered, save that of functional disorder. In both men barium chloride brought about a very rapid improvement in the cardiac state.

A point which seemed to me worthy of the remark was the character of the pulse wave produced. While its volume is increased it does not give that sensation of tenseness to the finger that does digitalis, and the pulse wave seems to be very considerably prolonged; a fact that the sphygmograph also records.

In most of the works on chemistry barium is stated to be an irritant poison, but to produce such evidences of its presence the dose given must be extremely large and *many* times greater than any amount useful for practical medicinal use.

What the verdict of the profession as to the general effects of barium upon cardiac disease will be, time alone will tell, but it is worthy of remark that in this substance we seem to possess a remarkably cheap, virtually tasteless, and very slightly poisonous drug, which, nevertheless, acts as rapidly as digitalis, and does not disorder the stomach.

[1] I am well aware that in some cases of slight aortic regurgitation exercise only will develop the Corrigan pulse. This case, however, had very typical signs of an advanced lesion.

MEDICAL PROGRESS.

Antiseptic Measures Adopted at the New York Eye and Ear Infirmary.—DR. W. F. MITTENDORF gives an account of some of the antiseptic measures adopted at the New York Eye and Ear Infirmary, Thirteenth Street and Second Avenue, which is as follows:

Of the different drugs employed, alcohol, corrosive sublimate, carbolic and boric acids are the principal ones.

Large bottles containing solutions of these chemicals are kept constantly on hand in the operating room. The solutions of corrosive sublimate vary in strength from 1 to 500 to 1 : 5000. The stronger preparations are usually employed to cleanse the operators' hands; the solutions of 1 : 2000 or 1 : 3000 are employed where an inflamed condition of the conjunctiva calls for greater precautionary measures, and the weaker solutions are freely used in cleansing the conjunctival sac both before and after operating in ordinary cases. Unfortunately, the irritating effect of the bichloride of mercury solutions upon the conjunctiva, and at times on the cornea itself, makes the use of this best of all antiseptics rather dangerous at times.

It soon became apparent after its use, in changing the bandage for the first time after cataract extractions, that, although the conjunctiva had been perfectly normal at the time of the operation, the eyes had an angry red appearance, due to injection of the conjunctival vessels, and not infrequently even a mucoid discharge was observed at these times, offering an inviting surface for germs that might be floating in the air and get into the eye at the time of changing and dressing. These facts, and the greater freedom with which milder, non-irritating solutions of other remedies may be used, have led most of the operators to use solutions of boric acid varying in strength from ten to twenty grains per ounce instead.

Carbolic acid is used principally for the cleansing of instruments and the disinfecting of sponges, although very few surgeons employ the latter, pledgets of absorbent cotton soaked in weak solutions of corrosive sublimate or boric acid being almost entirely used at present. Catgut is likewise preserved in carbolic acid. Absolute alcohol is used to immerse the instruments in before the operation, and biniodide of mercury in solution of 1 : 25000, although it enjoyed a great reputation, has only a very limited use at present; it being principally employed to cleanse the anterior chamber of blood and lens particles. Resorcin is very rarely employed by any of the operators.

Heat, dry as well as moist, is at times used for the cleansing of instruments that will not be injured by it,

for instance, those that are used for the removal of foreign bodies from the eye.

For minor operations the eye is washed out with a boric acid solution, applied freely by means of a soft rubber syringe. The operator and the assistants having washed their hands in a solution of corrosive sublimate, the instruments, which have been lying in alcohol for several minutes, are handed to him on a porcelain tray which had been cleansed in a solution of carbolic acid or corrosive sublimate. As soon as the operation is completed and the wound cleansed, the eye is washed again with an antiseptic solution and bandaged, if necessary, by placing over the thin layer of linen which goes next to the eye a sufficient quantity of cotton that had been previously moistened with an antiseptic solution, over this a layer of absorbent cotton, and over this the roller bandage is placed. In major operations, the eyelids and brows are washed with a solution of corrosive sublimate 1 : 2000, and the conjunctival sac is cleansed by washing it with a solution of either boric acid or corrosive sublimate, and some surgeons prefer to have this done several times before the operation in cases where there is a suspicious discharge from the conjunctiva or the tear passages. For this purpose a very much diluted Labarraque's solution of hypochloride of sodium is sometimes employed. Blood from the anterior chamber is usually removed by syringing the eyeball freely with Pannas's or a boric acid solution. The floor of the operating room is of hard wood, and the operating tables, as well as everything connected with the room, are kept scrupulously clean, a condition that should never be lost sight of, as a failure in this respect might counteract aseptic as well as antiseptic measures.—*International Journal of Surgery*, Jan. 1889.

Creasote in Tuberculosis and Catarrhal Affections.—Dr. Seitz, of Heidelberg, finds that, for tuberculosis and chronic catarrhal affections, creasote is best administered when mixed with cod-liver oil, as in the following:

℞.—Creasote . . . . . 38 grains.
Cod-liver oil . . . . . ℥viss.
Saccharin . . . . . 2 grains.—M.

Sig. One to four teaspoonfuls once, twice, or three times daily. For children, smaller doses should be given. —*Therapeutische Monatshefte*, Jan. 1889.

A New Locality for Trephining the Mastoid Process.—Dr. Mitzkuna proposes a new locality for trephining the mastoid process; the point of trephining to be found thus: The ear is drawn forward, whereby a fold (of the skin) is formed just behind the ear; under this fold a flat, bony prominence is felt; between this prominence and the base of the mastoid process is a depression, which depression is the place for trephining. The advantages of this locality over others are:

1. That a chisel can descend from one-fourth to one-third of an inch with safety.

2. That the transverse sinus, which takes a different course in different people, never touches this point.

3. That the thickness of the temporal bone is greatest at this point.

4. The only drawback of this locality is the possibility of going through the external auditory canal, but even this is nothing when compared to the possibility and danger of injuring the transverse sinus.—*Wiener klin. Wochenschrift*, January 17, 1889.

A Rare Cause of Dilatation of the Stomach.—Dr. Otto Pertik, of Buda-Pesth, describes and figures (*Virch. Arch.*, cxiv. 3) a singular abnormality, causing obstruction to the onward passage of the contents of the stomach, and leading thereby to great dilatation of the viscus. The defect consisted in a curious pouch of mucous membrane, shaped like the finger of a glove, about eight centimetres in length and three centimetres wide, which projected into the duodenum, with the upper part of which the posterior wall of the pouch was continuous. This first part of the duodenum was much dilated, and its mucous membrane quite smooth, passing continuously into the mucous membrane which formed the internal as well as the external coat of the abnormal pouch. The mouth of the pouch thus looked upward, and anteriorly it had a free lip or margin, close to which the common bile duct opened, suggesting the possibility of the formation of the pouch in an abnormality of the fold of mucous membrane that occurs at the orifice of the duct. But there was no evidence of gall-stone or any other cause which could have produced it. The probability is that the pouch was formed from one of the valvulæ conniventes, although the precise mechanism of its production is obscure. The entire absence of the folds from the dilated duodenum above the pouch may doubtless be ascribed to the distention which this portion of gut underwent in common with the stomach. In introducing the subject, Dr. Petrik makes some general remarks upon the etiology of gastric dilatation. Exclusive of congenital strictures of the pylorus, etc., he points out that the diminished power of the stomach to expel its contents may be brought about by: 1. Obstruction at the outlet—as from cicatricial or malignant strictures, hypertrophy of the muscularis or mucosa at the pyloris, polypi or tumors in the pyloric region, or external pressure on this part by tumors in the vicinity. 2. An actual loss of muscular power in the stomach, without any obstruction—as following on chronic catarrh, extensive ulceration, carcinomatous infiltration, peritonitic adhesions; and general conditions leading to loss of tone—as anæmia, typhoid fever, phthisis, etc. 3. An excessive amount of contents, as has been observed in the polyphagous, diabetics, and vegetarians; so that the pyloric orifice becomes relatively too small for the ready passage of the bulky gastric contents. The curious case related above falls, of course, under the first head, but the obstruction was in the duodenum, and not at the pylorus.—*Lancet*, Jan. 19, 1889.

Therapeutic Uses of Salicylate of Mercury.—Dr. Pulmert (*Vierteljahressch. f. Dermat. und Syphilis*, Heft 5, 1888), in his researches with salicylate of mercury, used the preparation from the factory of F. Heyden's successor, of Radebeul, near Dresden. It is a white amorphous powder, odorless and tasteless, of neutral reaction, and insoluble in water and alcohol.

To obtain a solution, the author mixed 10 parts of the salicylate of mercury with 15 to 20 parts of chloride of sodium dissolved in water; to this in turn were added 200 parts of water, and a solution obtained by heating the whole over a water-bath. The solution was then diluted

with 3000 parts of water, in which state of dilution the mercury would not separate. The prescriptions used were as follows:

For gonorrhœa:

℞.—Salicylate of mercury } āā 1 to 3 parts.
Carbonate of potassium }
Water . . . . . 1000 parts.

For external applications:

℞.—Salicylate of mercury } . āā 1 part.
Carbonate of potassium }
Water . . . . . 100 parts.

As a salve:

℞.—Salicylate of mercury . . 1 part.
Vaseline . . . . . 30 parts.

As a sprinkling powder:

℞.—Salicylate of mercury . . 1 part.
Carbonate of magnesium . . 20 parts.

For subcutaneous injections:

℞.—Salicylate of mercury } . āā 1 part.
Carbonate of potassium }
Water . . . . . 100 parts.

Internally:

℞.—Salicylate of mercury . . 40 grains.
Powder and extract of calamus, of each sufficient to make 1000 pills.

The results obtained with this preparation in the treatment of gonorrhœa were not as satisfactory as anticipated, the duration of the disease not being shortened by its employment.

Venereal and syphilitic ulcerations were covered with cotton which had been dipped in the one per cent. solution. (To avoid all possible eczema the cotton was not thoroughly saturated.) After two or three days the ulcers took on a healthy appearance, and healed rapidly. Syphilis proper was treated with subcutaneous injections of this preparation, which was used in proportions of 1 : 100. The injection fluid was always freshly prepared before each injection, special care being taken that the same was colorless, and without any deposit, sixteen minims were then deeply injected into the connective tissue. At first the patients would not complain of pain; after the lapse of a few minutes a slight burning sensation made itself felt, which lasted from one-half to two hours. Abscesses, the result of the injections, were never observed. Stomatitis was only observed in one case, and that was after the thirtieth injection had been made. Internally, the preparation was given in pill form. Digestive disturbances were not observed, while the results obtained gave great satisfaction.—*Centralbl. f. d. ges. Therapie*, Jan. 1889.

For Hæmoptysis.—

℞.—Ergotine (Bonjeau) . . 30 to 60 grains.
Gallic acid . . . . 8 grains.
Mint water . . . . ℥iij.
Syrup of oil of turpentine (Fr. Ph.) . . . . ℥j.—M.

This potion to be administered in teasponful doses in the twenty-four hours.—*L'Union Médicale*, Jan, 5, 1889.

Splenectomy in Spain.—DR. MAS, of Valencia, has performed splenectomy with an entirely successful result. This is the second time that the spleen has been extirpated in Spain, one other case having been done by Dr. Ribera Sans. Dr. Más's patient was a married woman who had had children. For some years she had noticed a tumor in the left loin the size of an egg, but after her last confinement this increased in size and caused a great deal of distress. On examination, a large smooth mass, giving the impression of containing liquid, and dull on percussion, could be made out in the left hypochondrium, the usual splenic dulness being absent. An exploratory puncture was made, and a clear, non-albuminous liquid obtained, which when examined proved to be of hydatid origin. The question then arose as to the organ in which it was seated. By a process of exclusion, the spleen was fixed upon as the affected organ, and it was also made out that it was both hypertrophied and out of place. The patient was extremely anxious that something should be done, and Dr, Más, knowing the danger of leaving such a tumor without interference, decided on performing splenectomy, having first satisfied himself that there was no leukæmia. He mentions that he was so affected by the preparations made for this important operation, and by the sight of the assistants who were to help him, that he almost fainted, and so, of course, was in no condition to operate at the time appointed. Three days later, however, he went to the house alone, gave the woman chloroform, lifted her on to a table, and extirpated the spleen, with a hydatid tumor as large as the fœtal head at term, without any skilled assistance. The wound was dressed antiseptically, and the patient made an excellent recovery, returning to show herself in first-rate health seven months afterward. The blood was examined at the time of recovery, and was found to show no signs of leukæmia.—*Lancet*, Jan. 19, 1889.

The Physician's Care of his Hands.—DR. GEORGE MEYER, of Berlin, writes (*Berliner klin. med. Woch.*, Jan. 14, 1889) that in these days when the physician is compelled to wash his hands frequently with disinfectants, they soon get into a deplorable condition. Redness, eczema, and small abrasions of the skin, the consequences of the frequent washing and brushing with antiseptics, are at times so annoying that in order to gain relief, temporary abstinence from the use of antiseptics seems the only remedy. Many methods have been resorted to, to render the hands soft and smooth; but one special method recommended to the author by Professor Liebreich seems especially worth mentioning.

After having washed the hands with soap, and thoroughly dried them, apply a small amount of lanolin; rub this over the entire hand, and remove *any surplus with a dry towel.* A small amount of perfume will render the preparation more acceptable. Thus, the following is very good:

℞.—Lanolin . . . . . 500 parts.
Vanilla . . . . . 1 part.
Oil of roses . . . . . 2 parts.—M.

Or,

℞.—Lanolin . . . . . 1000 parts.
Liquid paraffin . . . 250 "
Vanilla . . . . . 1 part.
Oil of roses . . . . . 2 parts.—M.

For the busy practitioner, such an ointment put up in metal capsules, like oil-paints, would be very useful. The author states that for years he suffered from lobster-red hands, which chapped as soon as the cold weather set in. Since using lanolin his hands have become white and smooth. He has recommended this remedy with similar benefit to actresses whose faces suffered from the application of cosmetics.

The *Archives de pharmacie* gives the following formula for lanolin cream:

℞.—Lanolin . . . . . 5 parts.
Sweet oil of almonds . . 5 "
Precipitated sulphur . . 5 "
Oxide of zinc . . . . 2½ "
Extract of violets . . . 5 "
Extract of alkanna (to give a rose color) . . 9½ " M.

Pregnancy and Operative Surgery; their Mutual Relations.—DR. LOUIS MCLANE TIFFANY, of Baltimore, in an article upon this subject, reaches the following conclusions:

1. Pregnancy is a physiological condition and does not contraindicate a surgical operation.

2. During pregnancy temporary strain may be exerted on some organ, *e.g.*, kidney, inducing impairment of function.

3. A surgical operation upon a pregnant woman is to be conducted so as to avoid inducing abortion, in itself a serious accident.

4. The main cause of abortion, or death after operation is sepsis.

5. The probabilty of sepsis after operation is increased if the patient is suffering from disease either temporary or permanent.

6. Abortion may result from shock.

7. Hemorrhage does not seem to induce abortion.

8. Union of fracture may be retarded by pregnancy.

9. Recorded cases show that the unborn child receives no evil impress when the mother is subjected to operation.

10. When a surgical operation upon a pregnant woman is under consideration, the function of all the patient's organs must be carefully investigated and regulated. An operation then conducted antiseptically may be expected to result as though pregnancy were not present.—*Maryland Med. Journal*, Jan. 26, 1889.

Local Treatment of Diphtheria with Salicylic Acid.—DR. A. D'ESPINE, in a paper upon this subject, concluded as follows:

1st. From the experiments made it is safe to say that salicylic acid, already in dilutions of 1 : 2000, is an excellent parasiticide of the bacillus of diphtheria.

2d. Its entire harmlessness in such doses permits its being used without fear, which cannot be said of carbolic acid or sublimate. Irrigations of salicylic acid should also be used as a prophylactic remedy in diphtheria, in all simple throat affections, which in time of an epidemic might be the means of receiving the bacillus of Löffler. This treatment should be especially applied to all scarlatinal sore throats, which, owing to the streptococcus of Heubner, might easily become the seat of necrotic pharyngitis or true diphtheria.

The author only claims originality for the large quantities of liquid used in the irrigations, which are repeated hourly until an improvement in the existing conditions is observed. It is evident that salicylic acid cannot prevent any accidents which are the outcome of an enfeebled constitution; hence the necessity of an early diagnosis of diphtheria becomes the more apparent.—*Revue médicale de la Suisse normande*, Jan. 20, 1889.

Action of Sulphonal.—At the clinic of PROFESSOR MEYNERT, at Vienna, sulphonal was administered to forty patients in 2 to 20 doses; the results obtained were good in 64.5 per cent. (that is, they obtained from six to eight hours' sleep), less good in 14.5 per cent. (sleep being frequently interrupted), and bad in 20.9 per cent. (little or no sleep being obtained). As a rule, the patient fell asleep from one-half to two hours after the preparation had been administered; evil after-effects, with the exception of an occasional headache, or a slight dizziness on awaking, were not observed.—*Wiener klin. Wochenschrift*, No. 2

Treatment of Migraine.—

℞.—Sulphate of quinine . . . gr. vj.
Crystallized salicylate of soda . " vj.
Chlorhydrate of morphia . . " ¼.—M.
For one powder.

Administer one powder every hour until four have been taken; then immediately after the last powder administer $\frac{1}{250}$ of a grain of aconitia. Generally from one-half to one hour from the beginning of this treatment the paroxysm will disappear.—*L'Abeille médicale*, Jan. 21, 1889

Treatment of Eczema of the Genital Organs.—

℞.—Oleate of cocaine . . . gr. 7 to 15.
Olive oil . . . . . ʒss.
Lanolin . . . . . ʒijss.—M
Apply twice daily.
—*Deutsche med. Wochenschrift*, Jan. 17, 1889.

Inoculation of Syphilis by Tattooing.—SURGEON F. R. BARKER reports that out of fifteen soldiers tattooed by one man eleven contracted syphilis. The men were tattooed at various dates during the year 1888, and the periods of incubation varied from eighty-seven to thirteen days. The operator was examined and found to have mucous tubercles in his mouth, a coppery rash on the chest, a scar on the penis, enlarged glands, etc. He admitted that he had mixed his colors with saliva and had also put the tattooing needles in his mouth.—*London Medical Recorder*, January 21, 1889.

Ingluvin in the Vomiting of Pregnancy.—DR. POPP (*Pester med. Presse*, No. 40, 1888) reports having achieved considerable success with ingluvin in the vomiting of pregnancy. Having a very obstinate case, upon which he had exhausted the entire resources of the pharmacopœia, he administered three times daily, one-half hour before mealtime, eight grains of ingluvin, and directly afterward two tablespoonfuls of a one per cent. hydrochloric acid solution. An improvement was observed after a few doses had been taken, and a cure effected after the treatment had been continued for three weeks.—*Deutsche med. Wochenschrift*, Jan. 17, 1889.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, FEBRUARY 16, 1889.

TUBERCULOUS MEAT AND MILK.

THE College of Physicians of Philadelphia, at its meeting held last week, discussed the subject of tuberculous meat and milk in their relations to the public health. The subject was introduced by Dr. George Strawbridge, who, in a paper containing a great array of statistics collected in Europe and in the United States, showed that tuberculosis is a common disease in cattle, especially in high-bred cows, and that under certain conditions it may be communicated to man by consuming the flesh and milk of animals suffering from this disorder. These facts, which are of universal importance, coupled with the discovery that no official inspection of meats and a very limited inspection of milk have ever been conducted in Philadelphia, should arouse intense popular interest in behalf of measures of protection against an apparently formidable source of a disease which is amongst the worst scourges of the human race.

It was the purpose of the lecturer to elicit, by a thorough discussion, the deliberate opinion of the College on this subject in the form of propositions which would serve as the basis for necessary legislation. These propositions were referred to a committee to report upon at the next stated meeting, when final action is expected to be taken.

The Congress on Tuberculosis of Man and Animals, held in Paris, July 25 to 31, 1888, the deliberations of which were fully reported at the time in THE NEWS, was perhaps the most important convention of the kind ever held. The conclusions adopted were accepted as definite and authoritative by the French government, which immediately adopted regulations to be enforced for the prevention of the transmission of tuberculosis from animals of the bovine species. Cattle are to be placed under the supervision of sanitary veterinary surgeons, and whenever found to be tuberculous are to be isolated and sequestrated, and when destroyed, the killing must be done in the presence of the officer. Meats from tubercular animals must be destroyed when the disease has become generalized, and also when the lesions are localized, if they have invaded the greater part of an organ, or appear in the form of eruptions on the chest-walls, or abdominal cavity. The sale and use of milk from tubercular cows is forbidden, though when boiled it may be used on the spot for feeding animals.

Dr. Strawbridge produced letters from veterinary experts and statistics which enabled him to state, that at least two per cent. of the animals of the bovine species in Pennsylvania are tuberculous. No official measures have ever been taken for preventing the sale and use of the meat and milk of such animals which are capable, under certain conditions, of communicating the disease to man. The danger of infection may be averted by thoroughly cooking these articles of food, but it requires a temperature of at least 185° F. to render them innocuous. Underdone meat is not heated beyond 122° or 140° F., and the practice of boiling milk is not the most common.

The danger having been pointed out, the next step is to determine upon the best measures of prophylaxis. Nothing should be left to haphazzard. The radical measures adopted by the French government are based upon well-ascertained facts, and would seem to meet the indications most completely.

This subject suggests a reference to the broad question of animal sanitation in its relations to the public health. It is a well-known fact that domestic animals are subject to numerous contagious and infectious diseases, some of which are intercommunicable between animals, whilst others are communicable to man. These diseases have at times proved very destructive, causing immense agricultural and financial losses to the country. The vast importance of a speedy extinction of these plagues has been recognized, and measures have been taken by the general government and by State authorities for

accomplishing this object, but these have been primarily adopted for the protection of agriculture. With some notable exceptions, no legislation has been adopted with the avowed purpose of protecting the public health. The meat from diseased animals is constantly exposed for sale in our markets, and statistics are not wanting to prove that the flesh and milk of diseased cattle are dangerous as food for human beings.

Professor Law states that malignant or contagious anthrax in cattle and sheep has become increasingly frequent throughout most of the United States in the past few years. The disease known as malignant pustule in man is acquired by consuming the flesh and milk of cattle thus affected. The resting spores of the bacillus anthracis may survive 300° F., and therefore ordinary cooking does not destroy their virulence.

Epidemic pleuro-pneumonia is also a common disease. Whilst doubt has been expressed as to the effect of this disease upon the meat, Gamgee and other excellent authorities affirm that the flesh of cattle thus affected produces disease in man.

The parasitic diseases of animals are not uncommon. The trichina in pork, the cysticercus cellulosæ in pork which produces the tænia solium in man, the cysticercus in cattle which produces the tænia mediocanellata in man, the cysticercus in sheep, the echinococcus in cattle derived from the tænia echinococcus in the dog, and communicated to man, and the rot in sheep, or fluke disease, caused by the distoma, are sources of infection which should be guarded against.

The milk, butter, and cheese from cows suffering with the foot-and-mouth disease may communicate the disease to man.

Facts and authorities might be stated to show how common is the existence of dangerous communicable diseases among animals, and that many of these affections can be transmitted to man, either by accidental inoculation or by consuming the diseased flesh and milk. It is time that concerted action should be taken for the protection of the public health against these sources of injury, as well as for husbanding the agricultural resources of the country. Local and State action is only of limited benefit. The subject is of so momentous a character as to demand the intervention of the national government, and it would appear to be a wise course to delegate the control of animal sanitation, especially the animal contagia and parasites which affect man as well, to a national board of health clothed with ample authority to investigate these diseases and apply measures for their restriction or extinction.

SOZOIODOL.

This substance differs in one respect from other antiseptics, so far as our patriotism is concerned, in that it was first made and employed by one of our own countrymen in San Francisco; but at that time the preparation of it was so imperfectly carried out that foreign matters made it too irritating for general use and it was discarded, only to be better prepared and more widely used in Germany, some years later.

In the *Therapeutische Monatshefte* for January, 1889, Nitschmann, of Erfurt, gives his experience, and that of others, in the use of sozoiodol. He finds that it is of value as an antiseptic and disinfectant in wounds which are in a diseased state, and in acute stomatitis and pharyngeal catarrh he employs it in the form of a five per cent. watery solution. He has also found it useful in acute, in purulent conjunctivitis, and in blennorrhœa neonatorum in the proportion of two parts of sozoiodal to thirty parts of water.

He treats urethritis, of a specific type, by employing the preparation known as zinc-sozoiodol in a two per cent. solution, and he also finds it of value in mild and malignant vaginitis, first using, by means of a speculum, an application of pyroligneous acetic acid or nitrate of silver.

In the treatment of gynecological cases, particularly in catarrh of the cervix uteri, Nitschmann uses sozoiodol in the form of a powder applied by means of a tampon with good results, and it would seem as being worth a trial in many other states of the mucous membranes than those just named.

DR. JOHN CALL DALTON.

The profession throughout the country will learn with the deepest regret of the death of Dr. John Call Dalton, which occurred at his residence in New York City last Tuesday.

Dr. Dalton was born at Chelmsford, Mass., on February 2, 1825, was educated at Harvard University, from which institution he received the degree of B.A. in 1844, and of M.D. in 1847. He early devoted himself to the study of physiology, and in 1851 his essay on the "Corpus Luteum of Pregnancy," which obtained the prize offered by the American

Medical Association, at once established his reputation as an able investigator in physiology. Shortly afterward he was appointed Professor of Physiology in the University of Buffalo, and, it is said, was the first in this country to use vivisection in class teaching. He resigned this chair in 1854 to accept a similar one in the Vermont Medical College, and three years later he accepted the chair of physiology in the Long Island College Hospital, and in 1855 he accepted the same chair in the College of Physicians and Surgeons of New York, which he held until 1883, when he retired from active teaching and accepted the Presidency of the College.

During the war he served in the army, first in April, 1861, as surgeon of the New York Seventh Regiment, and in August he was appointed brigade surgeon, and served until March, 1864, when he returned to New York City and reëntered upon his duties at the College of Physicians and Surgeons.

Dr. Dalton was a member of the National Academy of Sciences and of numerous medical societies. He was president of the Section of Physiology of the International Medical Congress held at Philadelphia in 1876.

Dr. Dalton was an earnest student and able writer. His "Treatise on Human Physiology," the first edition of which was published in 1859, has always justly enjoyed marked popularity, and was at once adopted as a standard text-book in all of our medical schools; it has gone through seven editions, the last having been published in 1882. He also wrote a "Treatise on Physiology and Hygiene for Schools" etc., which was published in 1868 and has been translated into the French Language; "The Experimental Method in Medicine;" "Doctrines of the Circulation;" "The Topographical Anatomy of the Brain," a beautifully illustrated atlas of which only two hundred and fifty impressions were printed, and copies of which are now highly prized.

In Dr. Dalton's death the profession has lost a member of the highest honor and integrity and one who by his character as a man and ability as a thinker, teacher and author, has largely contributed to the elevation of American medicine.

THE Secretary of War has issued an order relieving Surgeon George M. Sternberg from duty at Baltimore so as to afford him an opportunity of continuing his researches into the nature of yellow fever, and for this purpose Dr. Sternberg will visit Havana and other points in Cuba. He began these investigations over a year ago under a special act of Congress and visited Cuba and Brazil. Later he returned to Florida during the epidemic in that State and visited the infected locality. He will submit the results of his researches to the Secretary of War in a report that will probably be made next fall.

SURGEON-GENERAL JOHN B. HAMILTON announces that in view of the recent enactment of a law prohibiting any original appointments in the Marine-Hospital Service, except to the rank of Assistant-Surgeon, thereby practically creating a life-tenure in the office of Supervising Surgeon-General, he has resigned the editorship of the *Journal of the American Medical Association*, his resignation to take effect with the issue of February 9th.

THE College of Physicians of Philadelphia have awarded the William F. Jenks Prize for the best essay on the "Diagnosis and Treatment of Extra-uterine Pregnancy," to Dr. John Strahan, of Bedford, Ireland. The prize amounts to the sum of two hundred and fifty dollars. The successful essay, which we understand is quite lengthy, will be published in the *Transactions* of the College.

WE regret to learn that, on account of ill-health, Dr. Ménière has been obliged to suspend temporarily the publication of the *Gazette de Gynécologie*.

REVIEWS.

THE PROPRIETY OF SURGICAL INTERFERENCE IN PERFORATING TYPHOID ULCER. By J. EWING MEARS, M.D., of Philadelphia. Pamphlet, 8vo. pp. 14. Philadelphia: 1888.

This interesting pamphlet is a reprint from the *Transactions of the American Surgical Association* for 1888. The author submits the following propositions in the hope that the experience of the future may prove that the limits of surgical art can be so extended as to include in the list of justifiable and successful operations, laparotomy in certain forms of perforating typhoid ulcer.

1. Surgical interference is not justifiable and should not be instituted in cases of typhoid fever in which perforation occurs when the infective process is at its height. This conclusion is based upon our knowledge of the morbid conditions peculiar to and present in the disease, and the effects produced by them upon the general system.

2. In mild cases of the disease, in which the pyrexia has not been of high grade and in which perforation occurs at the end of the third week, or later, when the

stage of convalescence is fully pronounced, laparotomy may be performed. Surgical interference in cases of this character is advocated with the hope that if the method of operation suggested by Lücke—laparotomy with the creation of an artificial anus—be adhered to, success may be accomplished.

3. Rapidity in operation will be an essential factor in the achievement of success, through which prolonged exposure of the cavity will be avoided and shock greatly lessened. Median incision having been made, the hand should be passed to the position of the ileo-cæcal junction, the ileum seized, drawn into the wound, and examined as it is slipped through the hand, which should remain in the cavity. The perforation being found, the portion of intestine including it should be quickly sutured to the edges of the abdominal incision, the sutures being introduced at sufficient distances from the ulcer edges to insure inclusion of healthy tissues. Hot antiseptic solutions should be then poured, in sufficient quantity, into the cavity, a glass drainage tube carried to the floor of the pelvic cavity, and the wound closed. Prolonged "toilette" of the peritoneal cavity, as it is generally understood, should not be made while the cavity is open. Irrigations through the drain tube should be made as soon as the cavity is closed, and should be repeated at such intervals as the surgeon may deem proper. So extremely rare is the occurrence of double or multiple perforation that, after the discovery of one opening, further search of a critical and prolonged character may be safely omitted. As in the cases in which operation is deemed advisable, the perforation is not due to the extension, *per se*, of the ulcerative action, but to what may, almost always, be designated as a mechanical cause, the absolute quietude of the patient, which must be enforced, as well as the rest secured to the intestine by the operation for production of artificial anus, whereby the free escape of the feculent contents and gas is facilitated, will contribute largely to the prevention of further perforations. Should the patient survive, relief from the artificial anus can be obtained by operation.

SOCIETY PROCEEDINGS.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Eighty-third Annual Meeting, held at Albany, February 5, 6, and 7, 1889.

THE PRESIDENT, DR. SAMUEL B. WARD, of Albany, called the Society to order, and made a brief inaugural address.

DR. B. F. SHERMAN, after the transaction of some preliminary business, offered the following resolution in reference to

MALPRACTICE SUITS,

which was adopted.

Whereas, There is now a bill before the Legislature which requires those commencing suits for libel against publishers and editors to give bail for all costs; and

Whereas, Ninety per cent. of all suits brought for malpractice are for blackmail, therefore be it

Resolved, That the Committee on Legislation be hereby instructed to use all honorable means to have this bill amended so as to include cases of malpractice.

A number of papers were then read, of which our special correspondent has sent us abstracts as follows:

DR. JAMES B. HUNTER, of New York, read a paper on

THE TECHNIQUE OF VAGINAL HYSTERECTOMY.

Two points must be considered in the discussion of this subject, one as to the immediate result of the operation, and the other as to its permanent result. Both must be good in order that the operation may hold position as a justifiable surgical procedure. It has been decided for some time by comparative statistics that the immediate results of vaginal hysterectomy are not worse than those of many other major surgical procedures, and the recently published statistics of Secheyron seem to show that the permanent results in many cases are also good. The dangers of the operation arise from shock, hemorrhage, peritonitis, and septicæmia. As to the first of these, rapidity of operation seems to lessen the danger of shock in this as in other serious gynecological operations. The dangers from hemorrhage have also been greatly reduced since the introduction by Péan of hæmostatic forceps for clamping the broad ligaments. These are not only far easier of application than ligatures, but they are also more efficient and safer. In twelve hysterectomies, in which the clamp forceps have been used by the author, only two deaths have occurred.

The details of the operation, as given by the author, did not differ materially from those which are given by various operators. He advocated the use of creolin in a two per cent. solution as a dressing, and also the use of creolin gauze as a vaginal packing subsequent to the operation. If the ovaries or tubes came into view during the operation, they might be removed, otherwise they need not be disturbed. If clamp forceps were used, ligatures were seldom necessary, and as many as fourteen clamp forceps could be used if conditions required them. It was important to tie the handles of the forceps together as a safeguard against slipping. The gauze was usually left in the vagina four days, and then the forceps might also be removed. The author did not think it necessary to close either the vaginal or the peritoneal wound, and additional time would thereby be saved. In none of his cases had there been either hemorrhage or infection. He had not used the cautery as a hæmostatic, as he had never found it necessary; there was also some danger in its use to the intestines and other structures.

There was little discharge from the wound during the first week, and still less during the second. Patients were sometimes able to be about by the beginning of the third week. The hæmostatic forceps favor drainage, there is less danger to the ureters than with the ligatures, and they enable one to destroy diseased tissues which are not always accessible to the ligature. The longest forceps are not always the best, those with a bite of an inch and a half are sufficiently long, and one need not try to take in too much tissue with a single instrument.

DR. THOMAS A. EMMETT believed that an important point to consider was the duration of immunity from a recurrence of malignant disease which was to be obtained by such operations. If immunity could be obtained from two to four years, as it frequently was, he believed the operation was justifiable. Personally he was inclined to favor the supra-vaginal amputation of the cervix as sufficiently radical, and had obtained good results from such operations. He thought the radical

operation was indicated in sarcoma, while it was sometimes questionable in carcinoma. He was much in favor of an abdominal operation for extirpation of the uterus, a modification of Freund's operation, which had recently been performed by Dr. L. A. Stimson.

DR. ANDREW F. CURRIER thought that there must always be a difference of opinion among operators as to a preference for a partial or a complete removal of the uterus for cancer. One's conduct in such matters would be largely influenced by personal experience and predilections. Another indication for the operation of hysterectomy was obstinate prolapse of the uterus, especially in women who had passed the menopause, and in whom other measures for the relief of this condition had failed. The point which was advanced by the author of the paper as to the value of the hæmostatic forceps in shortening the duration of the operation of hysterectomy, was a valuable one, and one which could be readily appreciated by one who had experienced the great difficulties which were sometimes encountered when the ligature was used. As to the instruments which were useful in performing the operation, he favored those which were used by Martin, viz., the perineal retractor of Simon, lateral retractors, and a volsella in each lip of the cervix for drawing down the uterus.

DR. ANDREW F. CURRIER, of New York, read a paper entitled

THE DISORDERS OF MENSTRUATION,

which will appear in full in our next issue.

DR. A. JACOBI had seen many cases of so-called vicarious menstruation in young girls, manifested especially in the form of nose-bleed. He did not think this bleeding was always due to disorder of the pelvic circulation. It frequently came from heart weakness, especially in the case of schoolgirls who sat for hours at their tasks. He believed that in such cases treatment should be directed to the condition of the heart, and digitalis, sparteine, or strophanthus, in suitable doses, should be prescribed. He asked the author what he would do to restore, or to establish, the menstrual flow in such cases.

DR. C. E. LOCKWOOD, of New York, thought the special point in the paper was the improvement in the nomenclature of the symptoms heretofore expressed by the old terms amenorrhœa, dysmenorrhœa, menorrhagia, and vicarious menstruation. These have been loosely used to express a number of symptoms of, in great part, general and local structural, and in small part, functional, disease. They are largely symptomatic, and the names are unmeaning and indefinite in many connections in which they have been used. Etymologically, amenorrhœa means absence of the monthly flow, but it has been used not only in this signification, but also as expressive of defective or scanty and vicarious menstruation. By menorrhagia, is understood profuse monthly flow. Any suggestion which will reduce these terms to greater definiteness and system, and convey to the mind the condition and its etiology, is of value.

DR. HENRY C. COE, of New York, read a paper entitled

THE EARLY RECOGNITION OF CANCER OF THE CERVIX UTERI.

(See page 169.)

DR. A. L. LOOMIS, of New York, read a paper entitled

MANAGEMENT OF CARDIAC DILATATION BASED ON ITS ETIOLOGY.

In the diagnosis of heart disease, twenty years ago, murmurs were considered all-important elements. These and the various morbid changes of the valves by which they were caused, were the principal factors which were taken into consideration. Now they are only considered as adventitious sounds, which indicate the seat of certain valvular lesions. As long as the rhythm of the heart remains normal and the walls are in a normal condition, it is now considered that a heart is not in a serious condition. The heart may be hypertrophied, but this condition is compensatory, and indicates that the danger-line has not yet been reached. The tissues of the heart must be healthy, also the nerves by which it is supplied, and the blood which flows through it must also be healthy, in order to the well-being of the organ, and when these conditions are deviated from, there is weakening of the walls and dilatation. Serious heart disease, too, cannot be divorced from other diseased conditions with which they may be associated, such as general impaired nutrition, etc., conditions which are so commonly seen in poor workingwomen living on a diet of bread and tea. Such persons demand a change of diet, many hours of daily exercise in the open air, and suitable doses of arsenic.

In those cases in which dilatation results from softening of the cardiac muscle in convalescence from severe disease, patients should be kept in bed in the recumbent position, no exciting surroundings being allowable, and suitable doses of quinine and strychnia should be administered as long as the irregularity of heart action continues. In dilatation from fatty softening of the heart, angina and digestive disorders are frequent accompaniments; hence, the functions of the liver and stomach must be carefully guarded. Such cases demand spare diet and rest; or if exercise is indicated, it must be of the gentlest character. In their treatment calomel is appropriate, also arsenic, strychnia, and iron, the latter being given alone, never in combination. Digitalis should never be given. In an emergency a hypodermatic of morphia will be of great temporary benefit, also bichloride of mercury in doses of one-sixtieth of a grain. If Graves's disease is present, graduated doses of strychnia will be of great service. In the dilated heart which proceeds from excessive venery, the speaker had found good results from the daily use of thirty to sixty grains of bromide of potassium.

In all cases the life and habits should be carefully regulated, without the use of medicines. As long as hypertrophy continues, and when the venous system becomes engorged, large doses of the tincture or the infusion of digitalis should be used. This drug is always indicated as soon as loss of compensation with its attendant symptoms is present, for by this means the arterial pressure will be raised. It should be continued as long as the flow of urine is abundant, but it should be stopped when the urine begins to diminish. The quantity to be given will vary with the susceptibility of the patient, and the largest quantity should be given at bedtime. Squill increases the action of digitalis more than any other drug which can be combined with it, and its combination with calomel is also useful. The other cardiac tonics, strophanthus, convallaria, and adonidine,

do not have a diuretic action, and are not so useful as digitalis.

Dilatation from obstruction of the pulmonary circulation is always in the right heart, and is sometimes relieved by the use of leeches over the sternum, wet cups over the right lung, or the abstraction of ten or twelve ounces of blood from the arm. Atheroma of the heart walls, the aorta, and the coronary arteries is most frequently met in women, and when followed by dilatation is sometimes due to excessive recoil of the aorta. Remedial agents for this condition must be used promptly during the compensatory stage, and the bromide of potassium may be given with good results. In dilatation from venticular hypertrophy and arterial sclerosis, improvement of the blood must be sought by a vegetable and milk diet, by citrate of potash, colchicum, buchu, and other agents, which will assist in the removal of the nitrogenous matters from the body. If this is not successful, temporary relief may be obtained by the use of full doses of digitalis, but the usual course in such cases is rapidly downward.

DR. A. JACOBI thought there was one class of dilated hearts which had not been referred to by the author, namely, that which occurred not infrequently in young children. In the newborn infant the aorta is normally small. If the pulmonary artery is too small, the body would have too little and the heart too much blood. It would thus be over-nourished and a pathological condition would result. In such cases the arteries over the entire body may also be too small. This condition not infrequently results in general anæmia, chlorosis, and pernicious anæmia, and at the autopsies of such cases the heart is found dilated. As to the value of digitalis for dilatation of the heart, this drug is not simply a heart stimulant, it also nourishes the heart muscle. Small doses of it may be given for very long periods when there is a condition of general debility. Sparteine is also very useful; it acts promptly, and may be combined advantageously with digitalis.

DR. GEORGE M. STERNBERG read a paper on

THE ETIOLOGY OF CROUPOUS PNEUMONIA.

Acute pneumonia is now considered by the best authorities as an acute specific disease, one in which there is something special in the inflammatory process. The object of the author is to bring forward the history of the experimental evidence which bears upon this view of the etiology of the disease. The microörganism of the disease is widely diffused and is probably not acquired by personal contact. The disease may occur, however, as an epidemic in prisons or barracks, in villages or in single houses, just as is the case with cholera or yellow fever. The cases may bear no especial relation to each other, however, but simply have a relation to a common environment, like exposure to cold, alcohol, etc. The disease prevails over a wide area of the earth. Its direct transmission to those who are brought in contact with it, as attendants upon the sick, is probably of very rare occurrence. The specific microörganism is found in the buccal secretion of healthy individuals. It might be objected that this makes the argument concerning its pathogenic character untenable, but with our present knowledge this does not follow, for pus cocci, also the cocci of tetanus, are found among the healthy, but produce disease only under certain conditions. Traumatism is one of the essential factors to the production of this disease, the bacillus being also a component factor, and it is necessary that it be introduced into a favorable location, there being a wide difference in the susceptibility of the tissues to invasion. Other factors may be reflex vaso-motor paralysis of a part of the lung, which enables the microbe to do its work, also many changes in the cocci themselves which may change their pathogenic activity.

The coccus of pneumonia was described in 1882 by Friedländer, and in the same year by Leyden and Gunther. Matri published observations in 1883; and the same coccus was also found by him and others in different diseases. In 1882, Friedländer described the results of his experience with blood cultures, upon which the fact of the oval pneumococcus was established. Talamon also described to the Anatomical Society of Paris, in 1883, a few days after Friedländer's paper was read, a lanceolate coccus which he obtained from pneumonic exudate after death, or from blood drawn during life. He produced genuine lobar fibrinous pneumonia with pleuritic and pericardial complications with it in rabbits. This coccus is not identical with that which was discovered by Friedländer, but with one which was discovered by the reader from his own buccal secretions in 1880, and which was named by him *micrococcus Pasteuri*. He inoculated rabbits with it at that time with fatal results, but did not discover that his coccus differed from that of Friedländer until 1885. Fränkel found that the coccus of saliva (M. Pasteuri) more frequently caused pneumonia than that which was obtained from rusty sputum.

Weichselbaum's *diplococcus pneumoniæ* is also found to be a more frequent cause of pneumonia than is that of Friedländer. Gamaleïa concluded from extensive experiments in mice, and also from a review of the entire subject, that pneumonia is *usually* caused by the *micrococcus Pasteuri*. The author believed that many reports concerning the micrococcus of Friedländer should be credited to the *micrococcus Pasteuri*; for the two are entirely dissimilar as is shown by staining, Gram's method resulting in a discoloration of the former but not of the latter.

Experiments which have been performed with the *micrococcus Pasteuri* upon dogs and sheep were also described. The disease which was produced in them was far less fatal than in mice, showing far less insusceptibility to its virulence. In this respect pneumonia in dogs and sheep is similar to that disease in human beings. The probability is that in these higher animals the coccus does not invade the blood extensively. The author's early experiments, which were abundantly verified and published before those of the others mentioned, entitle him to the credit of the discovery of this microorganism.

DR. WILLIS E. FORD, of Utica, then read a paper on

GALVANISM IN GYNECOLOGY.

If a constant current of electricity be passed through living tissue certain changes are brought about, due partly to chemical decomposition and the separation of the fluids of the tissues and partly to a change in the nutritive processes produced by polarization of the ultimate molecules of matter. The results obtained depend wholly upon the character of the current used. From

the study of electricity itself and a proper appreciation of the various qualities of a current as much may be expected as from the study of the morbid conditions for which it is prescribed. Dynamic electricity of great volume or ampèrage is capable of great destructive power just in proportion to the quantity of zinc acted upon within the battery. While such a current may be capable of producing cautery effects it will not push its way through dense tissue for any distance. For this purpose a number of independent elements connected up in a series is necessary. The voltage or the pressure power of a current is as important therefore in therapeutics as is quantity or ampèrage. It has been found that a current that is strong enough to push its way through a fibroid tumor of the uterus as large as a cocoanut, must possess the pushing power or tension of from twelve to sixteen volts. If, therefore, the battery used for the purpose of dispersing fibroid tumors has this requisite voltage, the ampèrage may vary within certain limits and yet good results be obtained. A battery with large cells gives no greater voltage than a battery with small cells and small elements, while the ampèrage of the battery depends wholly upon the size of the elements used.

The author was convinced that one of the reasons why galvanism is not more generally and successfully used, is that portable batteries or batteries having but a single fluid, as they are constructed by instrument-makers, are wholly inadequate for the purpose. The two-fluid batteries, on the other hand, are so expensive that few practitioners possess them. The ordinary bichromate of potash battery, which is unquestionably the best form of battery, will answer every purpose if the cups in which the elements are immersed are sufficiently large that the current may not run down. Such a battery of fifteen cells holding a quart each, with some simple contrivance by which the zincs and carbons can be readily lowered into the fluid, makes a most perfect instrument for gynecological practice. The ampèrage, or volume of a current, is easily regulated by the depth to which the zincs and carbons are plunged in the fluid, while the tension, or voltage, or pressure of the current is regulated by the switch board, depending entirely upon the number of cells used.

The foregoing description has been thus minute, since the results in the practice of the author have seemed to depend largely upon the quality of the current. A galvanometer is of but little service, while a set of Brenner's resistance coils attached to the cabinet batteries is rarely used, the milliampèremeter being the chief guide. The volume of the current may be so large, however, that the latter is not always a safe guide; for instance, if a current from twelve cells is used, and the elements have an exposure to the fluid of forty square inches each, great care must be taken to prevent the vaginal electrode from cauterizing the tissue, even if the milliampèremeter marks but 100 or 150. There seems to be no guide, other than experience, regarding the safety of currents of large ampèrage. Where twelve or more such cells are used, the author had found it unsafe to have more than twenty square inches of zinc surface exposed in each cell, if the fluid is fresh. If pain is produced by the electrode in the vagina, it is evident that the limit of intensity has been reached. If the electrode is held firmly against a fibroid mass, and the voltage is increased until the milliampèremeter marks 150 to 200, and there is still no pain in the vagina, no harm will be done,

In removing the products of circumuterine inflammation, a current of large ampèrage will be the most efficient—that is, about 100 milliampères. The author's first paper upon the effect of galvanism in peritoneal adhesion, was published in the *Medical Press of Western New York* for April 1888, and stated what was believed to be entirely new at that time, namely, that peritoneal adhesions about the pelvic organs, and even about the abdominal viscera, can be effectually removed by means of the stronger galvanic current. These conclusions were reached from the behavior of fibroid tumors under treatment in cases in which there had been localized peritonitis with fixation both of the tumor and of the adjacent organs. Pain was speedily relieved, and the tumors became movable, even before there was any perceptible diminution in their size. This occurred so uniformly that it seemed evident that galvanism must be an efficient agent for the removal of organized inflammatory exudates. In the paper referred to, fifteen cases of fibroid tumor were reported, and four of peritoneal adhesions. Further experience has led to a modification in the method of using this agent, and also to the conclusion that the current used ought not to be the same in cases of simple hyperplasia of the uterus, or subinvolution, or in cases of chronic pyosalpinx, as in the denser fibroid tumors. In the latter, it has usually been found that a current generated from small cells, and having, therefore, comparatively small ampèrage, but high voltage, is the most useful. On the other hand, the same currents, when passed through a mass of exudative material surrounding or near the uterus, has in several instances excited a new inflammatory process, and has not secured ready absorption as in cases in which the current had greater electrolytic power, and in which the milliampèremeter marked only 80 to 100.

That a proper current of galvanism will stop the growth, and diminish the size of uterine fibroids, is no longer questioned, but how much may be accomplished by this agent in the removal of products of inflammation has not yet been fully determined. The author used galvanism in 64 cases during the year 1888, 31 being hospital, and 33 private cases. Of these, 19 were fibroid tumors of the uterus, 11 being sub-serous, 4 submucous, and 4 intramural. There were 5 cases of chronic pelvic peritonitis with extensive adhesions, 7 of localized pelvic peritonitis, in which the adhesions were limited to one locality, 4 of hydrosalpinx, 4 of chronic pelvic cellulitis, the exudate having matted the organs involved into one mass, 9 of retroversion of the uterus, with fixation, 10 of chronic metritis, 1 of chronic ovaritis, 3 of acute anteflexion with metritis. Of the 4 cases of hydrosalpinx, 1 discharged into the bladder, 1 into the rectum, and 1 into the vagina. In no case did a subperitoneal or an intramural fibroid disappear entirely, no matter how long the galvanism was used, but the growth was checked, and the troublesome symptoms disappeared. Very large masses, with accumulations of fluid about them, improved most rapidly, and the fluid disappeared in all cases. The current in such cases was of a strength of 200 milliampères, and was sent directly through the tumor, from side to side of the abdominal wall. In other cases, the negative electrode was placed in the vagina, against the projecting mass, the positive electrode being upon the abdomen, and consisting of a large dispersion plate of copper, covered with French punk and chamois.

Intramural growths are best treated by the abdomino-vaginal method. In two or three cases submucous fibroids disappeared, all bleeding being stopped, though that was not accomplished suddenly. It was not found that the positive electrode exerted a more beneficial effect than the negative, and the former was rarely used in the uterus or vagina. A current of 50 to 100 milliampères was all that was necessary to remove inflammatory exudates in every case, so that the conclusion was reached that persistency and skill were all that were necessary in such cases to ultimate success, if the general health were fairly good.

The fluid of a hydrosalpinx and the enlargement of an ovaritis will alike disappear by this means of treatment. In a few cases of acute anteflexion with chronic metritis, the platinum electrode has been passed just beyond the curve in the uterus, and has caused slight sloughing; with the use of a current of large ampèrage the result has always been satisfactory. If the patient is debilitated, and the exudate around the broad ligaments recent, inflammatory symptoms may occur if an attempt is made to cause absorption by galvanism. The author stated that he had never seen any harm follow the passage of the strongest current through the abdominal viscera. Healthy tissues, in which there is a normal quantity of fluid, furnish a good conducting medium for electricity, while the new connective tissue, which contains almost no bloodvessels, is a very poor conductor, and is thus susceptible to the effects of the current.

The author had not used the puncturing needle of Apostoli in any case, and he had had no serious accident, though he had frequently observed that the general health of the patient was not so good when under active treatment as previously, and also that it was sometimes two or three months after the galvanism was stopped before the full benefits of the treatment were appreciated. The number of applications should vary between twelve and twenty, and the intervals between them should be four days.

The following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—Daniel Lewis, of New York.
Vice-President.—Alfred Mercer, of Syracuse.
Secretary.—F. C. Curtis, of Albany.
Treasurer.—Charles H. Porter, of Albany.
Censors.—L. Emmet Holt, of New York; S. Sherwell, of Brooklyn; E. M. Hermance, of Yonkers; Joseph Lewi, of Albany; Thompson Burton, of Fultonville; Leroy McLean, of Troy; Robert Fraser, of Camden; C. L. Stiles, of Oswego; J. H. Glass, of Utica; H. L. Elsner, of Syracuse; Frank H. Potter, of Buffalo; B. R. Fordyce, of Union Springs.

CORRESPONDENCE.

A RARE COMPLICATION OF LABOR, SIMULATING RUPTURE OF THE UTERUS.

To the Editor of THE MEDICAL NEWS,

SIR: The extreme rarity of the accompanying case, occurring in the wards of Dr. Carl Braun, of Vienna, and sent to me by my son, Dr. J. Whitridge Williams, prompts me to forward it to you, with the request that you be kind enough to publish it in your valuable journal.

Yours truly,
P. C. WILLIAMS, M.D.

BALTIMORE, February 11, 1889.

The following case, which I was fortunate enough to see, in the wards of Dr. Carl Braun, of Vienna, is certainly worthy of mention, because of its extreme rarity;

A. B., pregnant with her eleventh child, entered the hospital after having been in labor for forty-eight hours. When I saw her, four hours later, she was in a state of collapse and had no labor pains.

On external examination we found that the abdomen, in the umbilical region, was of a yellow hue; and the lower portion of the abdominal cavity and the pelvis were filled with liquid in which the uterus could be freely ballotted *en masse*. The fœtus was dead, and presented by the vertex.

Naturally, from the condition of the patient, Dr. Braun diagnosed either a rupture of the uterus or a rupture of the vessels of the broad ligament.

Owing to the complete inertia uteri and a very small pelvis, craniotomy was performed, and the child extracted by the cranioclast. The placenta was extracted manually, and the interior of the uterus was examined with the utmost care, but no trace of rupture could be found In view of this fact, the diagnosis of ruptured broad ligament was made, and such diagnosis appeared to be correct at the time.

No exploratory incision was made, and death followed in fourteen hours. The autopsy revealed the pelvis filled with a *large quantity of bile*, which had flowed from a rupture at the junction of the common bile-duct with the hepatic duct, and had produced a general peritonitis, which caused death.

The uterine walls showed no sign of rupture, save at one point, where the uterine peritoneum presented, a short linear rent, which, however, did not extend into the muscular layer. No preëxisting inflammation or other cause for the rupture of the bile-ducts could be found.

I report this case on account of its great rarity. So far as I can learn, it is unique; and Dr. Braun states that in all his experience he has never seen or heard of a similar case.

Probably none of us will ever be required to diagnose between an acute hæmatocele and a case similar to this. Should we meet with an apparent case of uterine rupture, and find none, it would be well to remember that the bile-duct has been ruptured during labor with the production of similar symptoms, and that, in the case here reported, the lower part of the abdomen was stained of a yellow color, while the remainder of the surface was of normal appearance.

J. WHITRIDGE WILLIAMS.

VIENNA.

NEWS ITEMS.

Philadelphia Neurological Society.—At the annual meeting of this Society held January 28, 1889, the following officers were elected:

President.—Dr. S. Weir Mitchell.
Vice-Presidents.—Drs. Horatio C. Wood and Wharton Sinkler.
Secretary.—Dr. J. Madison Taylor.

Treasurer.—Dr. Guy Hinsdale.
Recorder.—Dr. William H. Morrison.
Council.—Drs. Charles K. Mills, Francis X. Dercum, and James Hendrie Lloyd.

An Unexpended Balance.—Press dispatches from Washington state that the unexpended balance of the appropriation by Congress to pay for medical and other service during the illness of the late President Garfield is about $10,000, and that Dr. D. W. Bliss, the chief physician in attendance on the President, and who received only $6,500, is a claimant for this unexpended balance.—*Boston Med. and Surg. Journal*, Jan. 31, 1889.

Honors to Pasteur.—The King of Greece has conferred on M. Pasteur the Grand Cross of the Saviour, the highest Greek order. Dr. Grancher, the director of the Pasteur Institute, and Dr. Roux and Dr. J. Guyon, assistants, are made Commanders of the same Order.—*Brit. Med. Journ.*, Jan. 26, 1889.

Accuracy of Diagnosis.—Lawson Tait says, in his recently published lectures on ectopic pregnancy and pelvic hæmatocele: "I once saw a surgeon, who is now a baronet and has a court appointment, remove a breast with a tumor in it. After he had the whole thing in his hands, he drew his knife across the tumor, and out spirted a lot of laudable pus. He had made his explorative incision after the treatment was complete. Absolute accuracy of diagnosis in the abdomen is very far from being possible; only the ignorant assert that it is, and only fools wait for it."—*Boston Med. and Surg. Journal*, Jan. 31, 1889.

The Potato-cure for Swallowed Foreign Bodies.—DR. SALZER, at a meeting of the Medical Society of Vienna, held January 11, 1889, stated that he had treated a six year old boy, who had swallowed a small weight, a woman, who had swallowed a set of teeth, and a nine year old girl, who had swallowed a nail, by the method advocated by Dr. Cameron of Glasgow, which consisted in feeding the patients for several days on nothing but potatoes. This treatment, which in all three cases was followed by success, is a method in vogue among the pickpockets of London, who swallowing their booty live on potatoes until the stolen articles appear *per vias naturales.—Berliner klin. Wochenschrift*, Jan. 28, 1889.

Massage and Masseur.—DR. METZGER, the famous masseur of Holland, puts himself out for no one. The Empress of Austria, and the princes and princesses who seek his treatment, must all go to him. The Pope is the only one with whom he makes an exception, the doctor going to Rome to treat him. He receives no one at his private residence; his clients, who come from all parts of the world, assemble twice daily in the drawing-rooms of the Amstel Hotel, and passing in their turn a few minutes with the doctor, they each and all submit to the special treatment adapted to their respective ailment, which treatment is generally successful. This celebrated specialist was formerly a butcher's boy; his careful observations of the muscular action of different animals, was the foundation of his success as a specialist.—*Progrès Médical*, January 12, 1889.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 5 TO FEBRUARY 11, 1889.

By direction of the Secretary of War, JEDEDIAH H. BAXTER, *Colonel and Chief Medical Purveyor*, will proceed to New York City on public business connected with the Medical Department, and, on completion thereof, return to his station in this city.—Par. 17, *S. O. 30, A. G. O., Washington*, February 5, 1889.

By direction of the President, JOSEPH C. BAILY, *Lieutenant-Colonel and Assistant Medical Purveyor*, and CHARLES L. HEIZMANN, *Major and Surgeon*, are detailed as members of the Army Retiring Board, at San Antonio, Texas, convened by War Department Order dated January 16, 1888, published in S. O. No. 12, January 16, 1888, from Headquarters of the Army, vice Lieutenant-Colonel Edward P. Vallum, and Major Francis L. Town, hereby relieved.—Par. 15, *S. O. 28, A G. O, Washington*, February 5, 1889.

The Medical Director will proceed to Fort Buford, Dakota, on public business connected with the Medical Department, and, upon completion of duty, will rejoin his station.—Par. 8, *S. O. 14, Headquarters Department of Dakota, St. Paul, Minnesota*, February 5, 1889.

By direction of the President, in pursuance of the authority contained in the provisions of the Act of Congress approved March 3, 1887, "Making appropriations for sundry civil expenses of the Government," etc., relating to the methods of preventing the spread of epidemic diseases, GEORGE M. STERNBERG, *Major and Surgeon* (U. S. Army), will proceed to the Island of Cuba, for the purpose named in the letter of the President addressed to the Secretary of War, April 17, 1888, and, upon completion of this duty, will return to his proper station, and submit his report to the President.—Par. 16, *S. O. 30, A. G. O., Washington*, February 5, 1889.

By direction of the Secretary of War, GEORGE M. STERNBERG, *Major and Surgeon*, is relieved from duty as Attending Surgeon and Examiner of Recruits at Baltimore, Maryland, to enable him to comply with the requirements of Par. 16, S. O. No 30, of the 5th inst.—Par 4, *S. O. 31, A. G. O., Washington*, February 6, 1889.

KILBOURNE, HENRY S., *Captain and Assistant Surgeon.*—Having complied with Par. 2, S. O. No. 6, Department of the Columbia, will return to his station, Vancouver Barracks, Washington Territory.—Par. 1, *S. O. 9, Headquarters Division of the Pacific, San Francisco, California*, February 2, 1889.

By direction of the Secretary of War, the leave of absence granted LOUIS A. LA GARDE, *Captain and Assistant Surgeon*, in S. O. No. 290, December 13, 1888, from this office, is extended three months.—Par. 2, *S. O. 31, A. G. O., Washington*, February 6, 1889.

By direction of the Secretary of War, ROBERT W. SHUFELDT, *Captain and Assistant Surgeon*, having appeared before the Army Retiring Board, at Fort Leavenworth, Kansas, in compliance with Par. 1, S. O. No. 4, January 5, 1889, from this office, will repair to this city, to await action on the proceedings in his case.—Par. 12, *S. O. 32, A.G. O., Washington, D. C.*, February 7, 1889.

MEARNS, EDGAR A., *Captain and Assistant Surgeon* (Fort Snelling, Minnesota).—Will proceed, without delay, to Fort Pembina, Dakota, and report to the commanding officer of that post, for temporary duty.—Par. 3, *S. O. 12, Headquarters Department of Dakota, St. Paul, Minnesota*, January 31, 1889.

MEARNS, EDGAR A., *Captain and Assistant Surgeon.*—Is relieved from temporary duty at Fort Pembina, Dakota, and will rejoin his station, Fort Snelling, Minnesota, without delay.—Par. 4, *S. O. 14, Headquarters Department of Dakota, St. Paul, Minnesota*, February 5, 1889.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING FEBRUARY 9, 1889.

HALL, J. H., *Passed Assistant Surgeon.*—Ordered to Naval Hospital, Washington, D. C.

ECKSTEIN, H. C., *Surgeon.*—Detached from U. S. Steamer "Adams," and wait orders.

DIXON, W. S., *Surgeon.*—Detached from special duty at Baltimore, Maryland, and ordered to the U. S. Steamer "Boston."

ORIGINAL LECTURES.

ACUTE PANCREATITIS.

A Consideration of Pancreatic Hemorrhage, Hemorrhagic, Suppurative, and Gangrenous Pancreatitis, and of Disseminated Fat-necrosis.

The Middleton-Goldsmith Lecture for 1889, delivered before the New York Pathological Society, Feb. 16, 1889.

BY REGINALD H. FITZ, M.D.,

SHATTUCK PROFESSOR OF PATHOLOGICAL ANATOMY IN HARVARD UNIVERSITY AND PHYSICIAN TO THE MASSACHUSETTS GENERAL HOSPITAL.

UNTIL the time of Clässen[1] the evidence of an acute inflammation of the pancreas was almost wholly theoretical, and was not controlled by any considerable number of anatomical observations. Mercury was known to produce salivation, and the watery diarrhœa following its use was supposed to be due to irritation of the pancreas.

Influenced by this and other considerations, Schmackpfeffer[2] having found certain alterations of the pancreas in a syphilitic woman who had been liberally treated with mercury, attributed her symptoms to the pancreatic changes. The latter he regarded as anatomical evidence of an acute inflammation. He describes[3] these changes as follows: "The pancreas was unusually dense, dry, and very much swollen; it was inflamed and red throughout, although more in the right than in the left side. Numerous drops of blood escaped from the cut surface. The duct was very much dilated, especially at its mouth. The gland weighed 5¾ ounces.

Some years later Neumann[4] stated that "death might take place within a few hours from a fatal metastasis of the buccal salivation to the pancreas. This happens when in the midst of profuse salivation the pulse sinks and quickens, or the swelling of the salivary glands subsides, and salivation is replaced by a green diarrhœa, while the skin is dry and shrunken." Under such circumstances the pancreas is found decidedly swollen, although but slightly reddened.

Clässen[5] knows of no observations in confirmation of Neumann's statement, and doubts its truth. He collects, however, a half-dozen cases, among them Schmackpfeffer's, of what he regards as fatal pancreatic inflammation, and from them he establishes the symptomatology of acute pancreatitis. The views thus obtained have essentially prevailed up to the time of Friedreich's article in Ziemssen's *Cyclopædia* in 1875.

The lesions found were as follows: In the second case, that of Juppin,[1] "a section was made through the pancreas. Its tissue was dense and friable. It was a third larger round than normal; it encircled two-thirds of the duodenum, which it compressed, and it affected the pylorus also. . . . The pyloric opening was almost entirely closed and the tip of the little finger could be introduced only with great difficulty and after repeated efforts. A vertical section through the pylorus showed it to be of almost cartilaginous density."

The third case is credited to Casper.[2] "All the organs of the remarkably handsome, though excessively fat, body were wholly normal with the exception of the pancreas. This was swollen to the size of a large fist, of cartilaginous density, firmly united to the duodenum, and in part to the stomach, and was of a brownish-red color. Its structure was not recognizable."

The fourth observation is also from Casper.[3] "The pancreas was so much enlarged that its head was a half hand's-breadth wide, much infiltrated with blood, very dense, its structure not recognizable. In consequence of the enlargement of the gland its shape was more globular then round.

Rahn is the authority for the fifth case.[4] The stomach was dilated "almost to bursting," and was filled with clotted blood. "In the middle of the abdomen there projected from the abdominal aorta a dense, scirrhous tumor as large as the fist. It was intimately united to the aorta, and so compressed it that when the aorta was opened the finger would not pass through the narrowed canal. The narrowed portion was immediately below the origin of the cœliac artery. On close examination of the tumor with reference to its origin, the head of the pancreas was found degenerated in this scirrhous mass, while the left part of the gland was in a wholly healthy state."

The sixth case is from Morgagni.[5] "The pancreas was unusually large, and contained round, tolerably large tumors of a density somewhat approaching that of cartilage."

To these is added another possible case, from Lieutaud,[6] in which, after an acute attack of gastric pain, fever, vomiting, anxiety, and frequent fainting, "the pancreas was found much enlarged, hard, and scirrhous throughout. The left kidney was in a state of liquefaction."

The first case may have been one of mercurial poisoning, the second was one of probable malignant disease; the third and fourth possibly of inflamed pancreas,

but the evidence is insufficient to establish clearly the diagnosis. The fifth case may have been one of aneurism while the last two are more suggestive of malignant disease than of acute pancreatic inflammation.

The common symptoms were deep-seated pain near the stomach, producing a peculiar anxiety, restlessness, perhaps frequent fainting. The pain bore no definite relation to the vomiting or other symptoms, and was not increased in proportion to external pressure. The vomiting was forcible, more or less greenish material being expelled. The abdomen was moderately tense, there was slight fever, and the appetite was but little disturbed and might be increased. There was a moist tongue, thirst, and constipation.

The effect of Clässen's treatment of the subject may be seen nearly thirty years later in the statement by Wardwell,[1] that the prominent symptoms of acute pancreatitis are deep-seated, dull, epigastric pain, distention, sickness, and vomiting of a clear, greenish, viscid fluid; thirst, faintness, moist tongue, constipation, and slight pyrexia.

The first step toward an essential modification of these views was made by Klebs, in 1870.[2] He preferred to say nothing about inflammation of the pancreas, but described the various lesions which have been found in and around this gland, without attempting to show their possible relations to each other. He availed himself of the cases published by Portal, Hooper, Löschner, Haller, and Klob, and of one in his own experience, to associate pancreatic hemorrhage with severe symptoms, and to recognize the possibility of a hemorrhagic inflammation of the pancreas, already admitted by Rokitansky[3] as a very rare occurrence. Klebs further recognized that this hemorrhagic inflammation might possibly result in a purulent peripancreatitis with partial sequestration of the gland.

Friedreich,[4] however, undertook to present a complete picture of acute pancreatitis more in accordance with the anatomical treatment of Klebs than with that of Clässen. He availed himself of the cases used by Klebs; in addition, of one reported by Oppolzer, and of another under his own observation. He suggested that acute pancreatitis was either primary or secondary. The former appeared to have a tendency to hemorrhage in the pancreas or in its vicinity, in which case a termination in gangrene and ichorous peripancreatitis might occur. If the acute pancreatitis became suppurative, multiple, minute abscesses were to be found, which tended to become confluent, and to produce a resulting peritonitis.

The secondary variety of acute pancreatitis was either the granular degeneration found in infective diseases, or the circumscribed "metastatic" abscess. The possibility of a metastatic pancreatitis in the course of a parotitis was not to be absolutely denied, especially in virtue of the case reported by Schmackpfeffer.[5]

As there is a doubt of the existence of a pancreatitis in this case, it may be safely stated that there is no reason for admitting the existence of a metastatic pancreatitis secondary to inflammation of the parotid gland. It is evident[6] that an acute parotitis may arise during the course of a pancreatic inflammation. This single instance of association is presumably analogous to the occurrence of parotid inflammation in septic conditions of various origin.

Since Friedreich's anatomical recognition of an acute pancreatitis was based upon the consideration of four cases, he admitted his symptomatology of this affection to be neither precise nor complete. Furthermore, he, seems[1] to include under the head of pancreatic hemorrhage those cases where this lesion is associated with necrosis and gangrene, and others where hemorrhage into the pancreas appears to be the sole cause of sudden death.

Klebs[2] had already recognized the existence of a suppurative peripancreatitis, and stated, presumably from his own observation, that in most instances this proceeded from lymph-glands. These were either the seat of metastatic abscesses, or were primarily diseased by traumatic agencies or injurious food. Such abscesses were regarded as occasional causes of thrombosis of the mesenteric and portal veins. He recognized a possible, eventual separation of the pancreas from surroundings by the extension of the suppurative process.

He thought it possible that the case of Haller and Klob,[3] already admitted as one of hemorrhagic pancreatitis, might belong in this series, and regarded that reported by Gendrin[4] as illustrative.

In the light of the observations published up to the time of his article, Klebs regarded as of doubtful existence any pancreatic abscess which did not arise from a peripancreatitis or from a suppurating cyst.

Important evidence as to the possible method of origin of a peripancreatitis was furnished by Chiari,[5] who found a round ulcer of the stomach communicating with the cavity of the omentum. The latter contained a spacious abscess with several openings into the jejunum. Lying free within this cavity was a shreddy mass of tissue, twelve centimetres long. It was brownish-black, friable, and presented the structure of the pancreas.

Four years later, Chiari published the report of a case[6] by Schlossberger, in which the sloughing pancreas was discharged through the bowels. He reported still another[7] of earlier occurrence, in 1862. The sloughing pancreas, discharged from the bowels, was brought to Rokitansky by Trafoyer.

The next communication of especial importance in connection with the subject of pancreatic inflammation is that of Balser.[8] He calls attention[9] to the presence of nodules and patches of necrotic fat tissue in the mesentery and in the contents of a cavity behind the mesentery. In the latter lay the pancreas also, attached only to the duodenum, and its lobules appearing as if macerated. A second case was reported by him,[10] in which there were patches of necrosis of the abdominal fat associated with similar appearances in the pancreas. In addition there was evidence of old and recent hemorrhage in the gland.

My own interest in this subject was first particularly aroused in 1876. At the request of Dr. J. P. Maynard, of Dedham, Mass., I made the post-mortem examination of a lady of uncertain age, not especially fat, who fell on the floor while apparently in her usual good health. She

died within thirty minutes. In the meantime, she complained of pain in the lower part of the chest. Her respiration became hurried, the pulse feeble; a short convulsion occurred, and death took place. The abnormal appearances found were several nodules and patches, the largest of the volume of a walnut, of freshly extravasated blood at the periphery of the posterior portion of both lower pulmonary lobes. There were several patches, of considerable size, of submucous hemorrhage near the ileo-cæcal valve along the mesentery. The pancreas was thin and very flaccid, with occasional slight, subperitoneal hemorrhages. Section through the organ showed similar hemorrhages in its substance. The gland-lobules were of a reddish-gray color, the general surface spotted with white specks. Microscopic examination showed extensive fatty degenerations of the gland-cells, many fat-drops being exceedingly minute. The interstitial fat was frequently crystallized, and, at times, bundles of orange, acicular crystals (hæmatodin?) were found.

The cœliac plexus was examined and nothing abnormal found. The heart was contracted, its cavities contained mainly fluid blood. The mesenteric veins near the cæcum were injected. The liver and kidneys were injected; the spleen and suprarenal capsules were normal. Nothing abnormal was found in the brain or heart. It was considered, at the time, that the history of the case and the appearances found were best explained on the ground of Zenker's communication,[1] which will be soon referred to more particularly.

Since then it has been my opportunity, largely owing to the zeal of Drs. Gannett and Whitney, to see at least a dozen examples of pancreatic hemorrhages, with or without necrosis of fat tissue, and of necrosis of fat-tissue without pancreatic hemorrhage. I have been present at several of the post-mortem examinations at which the diseased pancreas has been found, and have demonstrated to the students of the Harvard Medical School many of the specimens which have been removed by my friends and colleagues.

Having thus been impressed with the importance of the subject, I take this opportunity of utilizing the material which has been gradually accumulated by Dr. W. F. Whitney, the curator of the Warren Anatomical Museum. The value of this material is greatly enhanced by the records of the clinical course of the disease in question, which have been furnished by those in charge of the patients. In addition, a collection of similar cases has been gathered from medical literature, which of late years has been especially prolific in this subject.

This paper will include a consideration of—

The liability of the pancreas to hemorrhage;

The association of hemorrhage with acute pancreatitis;

The occurrence of acute pancreatitis without hemorrhage; and—

The relation of acute pancreatitis to fat necrosis.

Pancreatic Hemorrhage.

Although Kolb[2] regarded interstitial pancreatic hemorrhage as not rare, he found it only, and then not constantly, in extreme portal stagnation.

Spiess, however, in 1866,[1] reported to the Frankfort Medical Society a case[2] of sudden death due to an extensive, interlobular, pancreatic hemorrhage. His observation, though unique, escaped attention.

Klebs,[3] as already stated, had associated pancreatic hemorrhage with severe symptoms, and suggested that the hemorrhage might be due, in the absence of inflammatory changes in the interstitial tissue, to the corrosive action of the pancreatic secretion.

Zenker[4] then reported three cases as of fatal pancreatic hemorrhage. This lesion, however. existed in only two of them,[5] while in the third the hemorrhage was near the pancreas, in the hilus of the spleen. In this last case, and in one of the others, there was a striking venous injection of the solar plexus. He regarded this as the immediate cause of the sudden death, in accordance with the results of Goltz's experiment of cardiac paralysis by a blow on the frog's abdomen. He found, in one of his cases a flabby heart with distended, empty cavities associated with marked injection of the abdominal organs. as in the frog experimented upon.

Prince[6] then published a paper on this subject, and Draper reported[7] a series of cases of sudden death from pancreatic hemorrhage.

Virchow, however, in most recent times, has stated[8] that nothing is more rare than hemorrhage in the pancreas.

The relative frequency and absolute importance of pancreatic hemorrhage are thus, unquestionably, a discovery of very recent origin. There are, however, a considerable number of recorded cases which show that sudden and unexpected death may occur, and a conspicuous hemorrhage be found in or near the pancreas as the sole, significant lesion. Such hemorrhage may occur in a previously diseased pancreas or individual, or it may take place when the person is apparently in his usual health, and the pancreas gives no evidence of any acute disease.

Both groups illustrate the liability of the pancreas to hemorrhage, but the conditions of its occurrence must vary in each.

In the first series the hemorrhage is associated with certain lesions of the pancreas of a chronic character. The earliest case of this sort, and one which has been quoted in evidence of pancreatic hemorrhage as a cause of sudden death, is that by Störck.[9]

A woman, æt. twenty-eight, during the catamenial period, was seized with severe vomiting. The flow was arrested; chills, dyspnœa, and palpitation followed. Although she gradually improved, an epigastric pulsation became apparent synchronous with the heart-beat. After the next menstrual period this pulsation became more severe, and a resistant pulsating tumor could be felt below the stomach. The tumor increased in size, and there was a sense of weight in the epigastrium. During the subsequent three and a half months the symptoms improved, the palpitation became less, and the tumor smaller and softer. Sudden weakness then occurred, there was a rust-colored vomit, bilious stools,

sudden increase in the size of the tumor, rapid emaciation, and death,

The pancreas was found so large and heavy as to weigh thirteen pounds. It formed a sac filled with blood, partly grumous and partly laminated. The stomach, intestines, and omentum were displaced and compressed.

The evidence here presented is not sufficient to exclude the possibility of the chief lesion in this case being an aneurism of some artery in the vicinity of the pancreas. If Störck's view be accepted, that there was a hemorrhage within the pancreas, we have merely an illustration of what has been repeatedly found since his time, namely, hemorrhage into a pancreatic cyst.

The first indubitable case of this sort on record is to be found in the museum of the Harvard Medical School. It was published by Gross[1] from the MS. furnished by Dr. J. B. S. Jackson, and has also been published by the latter.[2]

For several months before the patient's death a tumor was noticed in the epigastric and right hypochondriac regions. There were also signs of advanced phthisis. The patient sat up every day until a short time before his death. The day before this took place he was found partially comatose. The tumor was a cyst of the pancreas, containing from ten to fourteen ounces of bloody-looking serous fluid without coagula.

The conspicuously hemorrhagic contents of pancreatic cysts have been also noticed by Anger,[3] Küster,[4] Bull,[5] Kocher,[6] Wölfler,[7] Hagenbach,[8] and Steele.[9] The case reported by Pepper[10] as one of fatal hemorraage from a pancreatic cyst admits of another explanation. The patient, an intemperate man, had frequently recurring intestinal hemorrhages for six months. He had two attacks of bloody vomit within five weeks, and, finally, an attack of gastro-intestinal hemorrhage, proving fatal in an hour. The blood came through an opening in the duodenum, a half-inch in diameter, near the common duct. A probe passed through the opening, entered a cavity in the head of the pancreas of the size of a walnut. Its walls were trabeculated, but "everywhere covered by a smooth mucous membrane;" numerous crystals of hæmatine were lying on the surface. "But little of the proper gland-tissue could be seen in this part of the organ, its place having been apparently usurped by dense, fibrous tissue. The same state of affairs is also observable in the body and tail of the gland, although in a less marked degree." It seems more probable, from the symptoms in this case, the seat of the cavity, the nature of the duodenal opening, and the history of pancreatic cysts, that this was rather a case of perforating duodenal ulcer with corrosion of the pancreas, than of pancreatic cyst opening into the duodenum.

Doubts are also to be entertained concerning Rugg's case,[1] reported as one of fatal hemorrhage from the pancreas. In 1843 he had a male patient, æt. thirty-two years, who was rapidly recovering from a severe attack of acute rheumatism, but was up and dressed on the day before his death. He had frequently complained of severe pains in the epigastrium, but these had left him a few days before his death, and were replaced by acute pains in the left lumbar region. He was suddenly seized with agonizing pain in the latter place. His countenance became anxious, his lips pale, pulse imperceptible, skin cold and sweating, and death took place in an hour. The pancreas was somewhat larger and harder than usual, and had a cavernous rupture in its anterior surface, having all the appearance of an excavated ulcer. Its cavity contained a bloody substance, about the size of a walnut, in concentric layers. On longitudinal section of the organ several of these sanguineous deposits were found, varying in size from that of a horse-bean to a hazel-nut, in appearance like aneurismal deposits. A large quantity of blood was extravasated over the left kidney. The probability of this case being rather one of aneurismal than of pancreatic hemorrhage is very strong.

Finally, the somewhat irregular case of pancreatic hemorrhage reported by Satterthwaite,[2] may be mentioned. The patient, a man of thirty-six years, intemperate, syphilitic, had three attacks of jaundice in eight years. The last began five months before, and continued until his death. Toward the end of life he had a persistent bleeding from the lip, frequent intestinal hemorrhages, and constant drowsiness. The pancreas was distended beyond the usual size by a clot of blood. There was an extravasation of blood between the coats of the upper part of the ileum. The symptoms in this case are so different from those occurring in immediately fatal pancreatic hemorrhage, or in hemorrhagic pancreatitis, that the hemorrhage may best be attributed to the jaundice, like that from the lip and from the intestine. The pancreatic localization of hemorrhage in jaundice is exceptional, but need not be unexpected.

There remains, then, the following series of sixteen cases where pancreatic hemorrhage was apparently the sole cause of sudden and unexpected death, in persons not presenting evidence of other causes of death. Nine of them have occurred in or near Boston, and three of these are now, for the first time, published.

The following more detailed report of Case XV. is compiled from notes sent by Dr. Holt, of Cambridge, who made the post-mortem examination.

The patient, fifty-eight years of age, was a gentleman of leisure, thin, white-haired, his body looking like that of a considerably older person. He was at a club-dinner the evening before his death.

He awoke about two o'clock the following morning, complaining of severe pain in the bowels, nausea, and great prostration. He was pale, and his pulse was very weak. He soon vomited, became collapsed, and died within half an hour.

The duodenal half of the pancreas was of a bluish-red color, and was sharply contrasted with the yellowish-gray splenic end. The darker portion was infiltrated with

SIXTEEN CASES OF PANCREATIC HEMORRHAGE.

No.	Authority.	Sex.	Age.	Antecedents.	Symptoms.	Lesions.
I.	Spiess, I., Schmidt's Jahrb. 1867, cxxxiv. 270.	M.	Adult.	.....	Sudden death.	Extensive, interlobular, pancreatic hemorrhage, and considerable hemorrhage behind the pancreas and spleen, between the peritoneum and abdominal wall.
II.	Klebs, Handb. d. Path. Anat., 1870, I. 2. 555.	...	...	.....	Unexpected death.	Extravasation of fresh blood in the pancreas, no interstitial inflammatory changes, no thrombosis of large vessels near pancreas.
III.	Zenker, Deutsche Zeitschr. f. prakt. Med., 1874, ii. 351.	M.	48	Very fat. Heart disease in early life. Previously pulmonary disease. Three years ago slight digestive disturbance.	Awoke suddenly at night; unwell; desire to defecate, got out of bed, slight tendency to vomit. Returned to bed. Immediate death.	Entire pancreas of an intense, bloody color, and so fatty infiltrated that only fatty detritus was visible. Slight cardiac aneurism not in such a condition as to be accused of causing sudden death.
IV.	Zenker, loc. cit.	M.	...	Drunkard.	Found dead in the water. Well on the same day.	Hemorrhagic infiltration and fatty degeneration of the pancreas.
V.	Maynard and Fitz MSS. notes 1875, v. p. 26.	F.	Adult.	In usual health.	Sudden pain in lower chest. Hurried respiration, feeble pulse. Death in a half-hour.	Thin, flaccid pancreas, with slight subperitoneal and intraglandular hemorrhages. Cut surface dotted with white specks. Extensive fatty degeneration of gland cells. Fat-crystals and blood-crystals. Nothing abnormal in cœliac plexus.
VI.	Kollman, Aerztl. Intell. Bl., 1880, xxvii. 427.	F.	Adult.	Mitral stenosis. Pleurisy in left chest. Frequent abdominal pain. Able to work.	After a hearty meal frequent, solid dejections. Restless and anxious at night. Cold. Sense of constriction in chest Ate breakfast with appetite. Died suddenly while walking with companions.	Injected pancreas surrounded as far as the spleen with extravasated blood. Hemorrhage in mucous membrane of the duodenum. 400 grammes of yellow fluid in left chest; 100 grammes in the pericardium. No appearance of fatty degeneration of the pancreas.
VII.	Gerhardt, V. Kollman, loc. cit.	F.	47	Bronch'l catarrh, emphysema, anasarca, ascites, albuminuria, cyanosis.	Died in collapse.	Inconsiderable, interlobular pancreatic hemorrhage. Tissue behind pancreas as far as the spleen infiltrated with blood. Duodenal mucous membrane almost black, and peritoneum over its convexity infiltrated with blood. Ecchymosis in mucous membrane of cæcum
VIII.	Reynolds and Gannett, Boston Med. and Surg. Journ,, 1885, cxii. 275.	M.	66	Abundant fat tissue.	Suffered from epigastric pain and constipation. Felt better next day, but in the evening found pulseless and collapsed. Death within 36 hours from the attacks of pain.	Pancreas enlarged one-half Consistency diminished. Cut surface reddish-black from much extravasated blood nearly uniformly distributed. Bloodvessels and pancreatic duct unaltered.
IX.	Draper, Trans. Asso. Am. Phys., 1886, i. 143.	M.	45	Strong, rugged. Drunk at long intervals.	Found dead in chair, as if asleep. Seen well within 48 hours.	Pancreas infiltrated with and surrounded by extravasated blood.
X.	Draper, loc. cit.	F.	44	Addicted to liquor, though rarely drunk.	Found dead in bed, to which she went dressed, complaining of headache. Seen well within 30 hours.	Pancreas infiltrated with blood. Moderate retroperitoneal hemorrhage. Eight ounces of thin, red fluid in the peritoneal cavity.
XI.	Draper, loc. cit.	F.	26	Very fat, intemperate. Kicked in abdomen a week before death, but afterward appeared in usual health.	Went to bed complaining of great abdominal pain. Some hæmoptysis. 14 hours later cold, pale, pulseless. Mind clear. Complained of intense abdominal pain and of thirst.	Pancreas enlarged, sodden, soft, and slimy, filled with effused blood. Infiltrated blood behind mesenteric peritoneum behind and below stomach, between stomach and colon, over right kidney. Twenty-two ounces of thin, red fluid in abdomen. No peritonitis.
XII.	Draper, loc. cit.	M.	55	Exemplary habits	Well in the morning. Cramps in the forenoon. Found dead eight and a half hours after.	The abnormally large pancreas uniformly infiltrated with fresh blood. Subperitoneal tissue of each side of the pancreas, for about two inches, filled with blood.
XIII.	Draper, loc. cit.	M.	31	Intemperate.	While in good health, sudden, epigastric pain, nausea, collapse and death in 45 minutes.	Pancreas and adjacent tissue infiltrated with blood; with microscope, granular gland-cells and blood in interlobular tissue.
XIV.	La Fleur, Méd. News, 1888, liii. 80.	M.	50	Obscure dyspepsia for several years.	Severe epigastric pain, vomiting, collapse. Death in 24 hours.	Pancreas doubled in size, dark red, firm. The cut surface mottled with capillary hemorrhage, separated by a grayish red, translucent material. Fatty degenerated tubules and acini. Cellular tissue around pancreas blood-stained.
XV.	Driver and Holt, MSS. notes, 1888, v. p. 52.	M.	58	At a dinner party the night before his death. Thin.	Awoke at 2 A.M. with severe abdominal pain, nausea, weak pulse and prostration. Speedy vomiting, collapse. Death within half an hour.	Duodenal half of the pancreas infiltrated with blood. Each side of the heart contained a little fluid blood.
XVI.	Williams, MSS. notes, 1888, v. p. 55.	M.	70	Thin, temperate, always well.	Sudden epigastric pain, vomiting, weak pulse, slight epigastric swelling, collapse in a few hours, and death in 16 hours.	Tail of pancreas infiltrated with blood. Slight mesenteric hemorrhage. No evidence of peritonitis.

blood, which lay in the interlobular tissue, and could be readily squeezed from the cut surface.

Nothing abnormal was found in the brain. Both sides of the heart contained a little fluid blood; the valves, cavities, and muscular substances appeared normal. The stomach was empty, and in the intestines were the products of digestion. The liver was normal in size and appearance, and the cortex of the kidneys was paler than the pyramids.

I am indebted to Dr. Williams, of Charlestown, Mass., for the notes of Case XVI., which occurred in his practice. It is included in the series, with the full recognition that it is open to criticism since the post-mortem examination was necessarily partial and hurried.

The patient, a man seventy years old, was a night watchman. His health had been good, and he had wholly abstained from liquor since early manhood.

In the evening he was suddenly seized with colicky pain in the epigastrium. After a few hours the pain was almost constant, sharp, and cutting, extending toward the left and down nearly to the navel. The abdominal muscles, especially the recti, were very rigid. There was a slight, circumscribed, epigastric swelling at the left of the median line, extending from the costal margin to the navel. It was non-resistant, and not sensitive to pressure, which rather relieved than increased the abdominal pain.

There had been vomiting of a yellowish fluid. The pulse was 95, regular, small; the radial and temporal arteries were rigid; the skin dry and not cool. The vomiting persisted, and in six hours the patient was collapsed, but conscious. He then became restless, the pain was less agonizing, and death took place sixteen hours after the beginning of the attack.

Dr. Williams's diagnosis was pancreatic hemorrhage. After death he was allowed to make an incision over the tumor, and found the pancreas enlarged from the median line of the body to the splenic end of the gland. The enlarged portion was more easily cut than the rest, and infiltrated with blood. On section, two or three ounces escaped into the peritoneal cavity. Slight mesenteric hemorrhages had occurred. There was no evidence of peritonitis, nor was any blood found in the peritoneal cavity before the pancreas was incised.

The following case, reported by Zenker,[1] is not inserted in the table, since it is not, strictly speaking, one of pancreatic hemorrhage, though important in suggesting the possible manner of death in this affection.

A man, aged twenty-eight years, strong, very fat, and epileptic, was found dead, having been seen alive an hour before. There was a hemorrhagic infiltration in the hilus of the spleen, and a venous hyperæmia of the solar plexus. The abdominal organs were injected, and the pancreas was in a state of fatty degeneration.

The consideration of the above table shows that most of the individuals concerned were in their usual health at the time of the attack, or when last seen alive. They were invariably adults, and usually beyond the age of forty, when the age was given. Some were conspicuously fat and strong, while a few were weak and thin. Although several were of intemperate habits, others were not so reported, and two were exemplary in this respect.

[1] Loc. cit.

Two had complained of previous digestive disturbance, and one suffered from frequent abdominal pain. One had received a kick in the abdomen a week before death.

From the evidence here collected, there is evidently nothing in sex, habit, condition, or exposure, which will indicate the likelihood of pancreatic hemorrhage.

The cases and data are insufficient in number and detail to permit an exact clinical picture of this affection which shall be of especial value in differential diagnosis.

We learn that pain was an early symptom in nearly one-half of the cases; that it was usually severe, and might be intense, and was to be found in the abdomen or lower chest. Although mention is made of its presence in the epigastrium in one-fifth of the cases, this region is not conspicuously designated as the seat. On the contrary, there may be little or no pain, or merely a sense of constriction of the chest. Nausea or vomiting is but occasionally mentioned; constipation or a desire for frequent stools is still more rarely noted.

The most constant symptoms are those of collapse, and are more or less intense and more or less prolonged.

Death may take place within a half-hour after the onset of the symptoms and may be delayed for thirty-six hours. It is questionable in the latter instance whether the case should not, more properly, be included under the head of hemorrhagic pancreatitis than of pancreatic hemorrhage.

The appearances found after death are conspicuously of hemorrhage within and near the pancreas.

The gland may be of normal size, or enlarged, and its density may not be modified, or the pancreas may be flaccid, soft, and friable. The hemorrhagic infiltration is to be found in the subperitoneal tissue around the pancreas as well as in the interstitial tissue of the gland. The former may be continued into the omentum and mesentery, behind the colon and into the perinephritic fat-tissue. The entire pancreas may be infiltrated, or either half, or the central portion alone may be conspicuously involved. The hemorrhage is usually diffused, but it may be in numerous patches, both beneath the peritoneal investment and in the interlobular tissue. The color and moisture of the cut surface indicate that the extravasation is recent. It may take place into a normal pancreas or into one which is either fatty infiltrated, or fatty degenerated, or into one which shows a granular condition of the epithelium.

In a single instance evidence of an older hemorrhage was to be found in the presence of round, orange-colored bundles of acicular crystals. In the same pancreas were also to be seen colorless, acicular crystals, probably of fat, in clumps visible to the naked eye, corresponding to the appearances to be described under fat-necrosis. The microscopic examinations of one of Draper's cases showed occasional patches of hemorrhage within the lobules, although the infiltration was essentially in the interlobular tissue.

Hemorrhages might also be found in the wall of the duodenum and cæcum, and in the lungs in a single instance.

Although the splenic artery is reported to have been tortuous in one case, there is no evidence in any of a circumscribed aneurism. The splenic vein, when examined, was free from obstruction.

The conditions found by Zenker, viz., injections of the

portal venous system and of the capillaries of the solar plexus, with distended and empty cardiac ventricles, were not generally met with.

Fatty degeneration and fatty infiltration of the pancreas were not necessarily present in these cases, and frequently occur without a trace of hemorrhage.

The seat, extent, and rapidity of the bleeding suggest that it is rather arterial than venous, and no evidence of venous obstruction has been found. Such hemorrhages are most likely to be of aneurismal origin, but aneurisms have not been discovered. An embolic source has been sought for in vain. It is possible that the pancreatic secretion may have corrosive properties, as suggested by Klebs, in which case the condition should occur oftener. Suggestive evidence in favor of this view is the fact, well known to demonstrators of anatomy, and called to my attention by my colleague, Dr. Mixter, that arterial injections are likely to break through and escape in the region of the pancreas.

Hemorrhages in a diseased or dead pancreas might be thus explained, but in the great majority of the cases collected there is no sufficient evidence of such disease. It is also possible that the hemorrhage may be of nervous origin as in the pulmonary infarctions sometimes associated with cerebral lesions.

The only fact in favor of this view is the association of such pulmonary nodules with the pancreatic hemorrhages in one case. This observation, compared with the relative frequency of pulmonary hemorrhages of apparent, central, nervous origin, makes the single instance of but little value as evidence.

That fat-necrosis is not a cause for such hemorrhage is obvious from its presence being suggested in only a single instance.

It is evident that the first step toward a more accurate knowledge of the immediate cause of this affection must lie in a more careful search for the actual source or sources of the leak.

(To be continued.)

ORIGINAL ARTICLES.

THE PREVENTION OF SUMMER DIARRHŒA AMONG INFANTS, VIEWED IN THE LIGHT OF THE LESIONS.[1]

BY L. EMMETT HOLT, M.D.,
OF NEW YORK.

THE purpose of this paper is to call attention to the fact that many of the so-called dyspeptic intestinal catarrhs of infancy, commonly looked upon as merely functional in character, produce lesions of considerable moment. These lesions are of importance, not so much in their immediate effects as in their relation to the severer forms of disease, particularly entero-colitis.

My attention was first drawn to these cases by two autopsies made last summer upon infants ten months old. One child died of acute pneumonia without intestinal complications. Throughout the large intestine the solitary follicles were very much increased, both in size and in number. In some places they were so numerous as nearly to cover the mucous membrane. This enlargement was at the expense of the rest of the mucous membrane. The follicles were eroded at their summits in many places, and looked as though they were beginning to ulcerate. Some of these erosions might have been produced accidentally in mounting the specimen, but many were present when it was removed from the body.

During the first five months of life, the mother stated that the infant had never had normal movements from the bowels; the passages were green or greenish-yellow, nearly always containing mucus, but were never frequent, at most three or four daily. The child was nursed entirely, and as the general health did not seem to be affected, and it gained steadily in weight, the mother did not think this intestinal catarrh of sufficient importance to call the resident physician's attention to it, although he saw the infant daily. The passages gradually became normal without treatment, and during the last five months before death had continued so.

The second case was that of an infant who was injured by falling from a window, and died within an hour. In this colon almost the same condition as seen in the first case was found to exist. The patient had never suffered from acute diarrhœa, but for nearly three weeks before death its stools had been very much of the nature previously described. Nor in this case had the mother regarded the fact as of any importance.

Microscopical examination in these cases revealed very slight catarrhal changes, but the important feature was the great enlargement of the solitary follicles.

Further experience in the examination of the intestines in patients dying from other diseases, usually pneumonia, confirmed the impression made by the first two cases, viz., that a dyspeptic intestinal catarrh (I use this term for want of a better) produces, when it is allowed to run on, marked alterations in the walls of the intestine.

If we examine a child's intestine some months after a sharp attack of entero-colitis, we find a very similar anatomical condition.

In cases of acute entero-colitis, dying after ten or twelve days' illness, the most constant change found is swelling of all these solitary follicles with, in many places, the formation of small circular ulcers from the breaking down of these follicles.[1] We conclude then that this condition of the solitary follicles such as we have described as occurring in dyspeptic catarrh, has a very intimate relation to follicular colitis. We may, perhaps, be justified in regarding

[1] Read before the New York State Medical Society, February 5, 1889.

[1] Photographs of specimens illustrating these lesions were shown.

it as identical with the first stage of the ulcerative process. The swelling in both cases is most likely due to the same cause, the absorption of ptomaines produced by the intestinal decomposition.

The intestines of infants are normally peculiarly rich in lymphoid masses, which, in disease, proliferate with great rapidity. These lymphoid nodules play a very important part in the pathology of the intestines in infancy. The enlargements take place here from slight irritation when continued, just as in the lymphatic glands of the neck; all the more readily if the patient is delicate or cachectic.

Turning now from the pathological to the clinical side of the question, what do we find?

Meinert, of Dresden, in a paper published last year, and extensively quoted, states that of four hundred and seventy-nine fatal cases of diarrhœal disease occurring in that city "seventy-one per cent. had previously healthy digestive organs." His information was obtained from the physicians who treated the cases and gave the certificates of death. The information of physicians under such circumstances we may safely assume would relate to acute or severe forms of gastro-intestinal disease, since mothers do not, as a rule, attach any importance to the dyspeptic intestinal catarrh we are considering. We cannot, therefore, it seems to me, attach any importance to Meinert's statistics as bearing upon the point under discussion.

In the New York Infant Asylum we have under close observation nearly four hundred children, most of them from the time they are a few weeks old until four years old. Our experience there has been that the great majority of all severe and fatal forms of entero-colitis in summer are preceded often for weeks by a "dyspeptic catarrh." Very often, I am sorry to say, this fact is not discovered until severe symptoms have developed, so little importance do the mothers attach to the disorder, particularly if the infant happens to be teething.

An idea of the frequency of follicular ulceration may be gained from the following statistics: Of fifty-seven autopsies I have made recently upon children dying from diarrhœal diseases, follicular ulceration existed in nineteen, or thirty-three per cent. of the cases. In almost every case the solitary follicles were very much enlarged. These cases presented clinically about all the types met with, and since they were, with but few exceptions, taken consecutively in an institution where all fatal cases come to an autopsy, they may be assumed to represent pretty fairly the frequency of the different lesions. (I need scarcely say that cases of tubercular ulceration have not been included.)

I will not enter here upon the discussion of the subject of intestinal decomposition and the development of abnormal bacteria, not because I underestimate its importance, but because my present purpose is to emphasize the other aspect of the question. The lesions, while no doubt aggravated and possibly primarily caused by the bacterial growth, when once present favor it to a marked degree.

It has been too much the fashion recently to think only of intestinal decomposition and not at all of the lesions with which it is so intimately related.

I have spoken chiefly, so far, of changes in the solitary follicles. They are never found unaccompanied by catarrhal changes, but the latter are in most instances of a much milder type and not likely to be so persistent. Follicular changes are slow in disappearing. This explains the long continuance of what are apparently very mild cases of intestinal catarrh, and the frequent relapses after more acute attacks.

The practical bearing of the foregoing remarks is evident:

The treatment of follicular ulceration of the intestine is extremely unsatisfactory. I believe that the great majority of these cases are fatal. Certainly, I have never seen at autopsy in a child anything which resembled a cicatrized follicular ulcer.

Successful treatment must be in the nature of prevention.

Prevention must have regard to all the milder intestinal catarrhs.

Regarding neglected diarrhœas during dentition, so much has been said recently that it is scarcely necessary to enter here again a protest. There is to my mind no more reason why an intestinal catarrh should not be treated, and, if possible, cured during dentition than at any other time. The fact that a child with whooping-cough is extremely liable to bronchitis and pneumonia has never been given as a reason why these complications should not be treated promptly and energetically when they arise.

Is an intestinal catarrh ever salutary? This is questionable. A number of loose movements may be of advantage to expel undigested food or other irritating materials from the intestine, but that a persistent intestinal catarrh, even if not severe, is an advantage to any child at any period remains to be proven.

The medical profession should take strong ground against the prevalent popular opinion, that so long as the general health is not affected, an intestinal catarrh is not only of no importance, but may, during bronchitis or dentition, even be beneficial, and that to cure it might be injurious.

It is in such cases as these that though amenable to proper treatment in the earlier stages, when allowed to run on, as they often are for weeks or even months, the foundation for grave and even fatal forms of diarrhœal disease is often laid.

The prophylactic treatment involves then the early recognition and intelligent treatment of all the forms of dyspeptic catarrh; in other words, it

means that we must secure proper digestion, and this depends chiefly upon proper feeding.

Out attention has been repeatedly called of late to the importance of seeing that our milk and other infant foods are pure and free from germs and putrefactive products. This is all important. Another danger which has not been often enough emphasized is overfeeding.

During the past two years I have been trying to get at some exact data regarding the proper amount of food which an infant, who is artificially fed, should receive at the different periods. This has been studied, first, by measuring carefully at autopsies the capacity of the stomach; and, secondly, by weighing healthy infants who were nursed at proper intervals, before and after they were put to the breast.

While I have not yet accumulated sufficient statistics for publication, still enough has been learned so far to show that the figures given in most of our books are altogether too large, and that the vast majority of hand-fed infants are *very greatly overfed.*

Difficulty and failure may result from this fact where every other condition for success has been attended to.

In conclusion I would emphasize the following points:

1. Children should not be overfed at any time, but especially not in summer.

2. At this season, also, every dyspeptic catarrh should be attended to; many of these are promptly curable by merely clearing out the intestine and then cutting down the quantity of food.

3. Should an intestinal catarrh, even a very mild one, continue for two or three weeks, one may be pretty certain that he has something more than a functional disorder to deal with.

4. Every mild catarrh should be looked upon as the possible precursor of a severe type of intestinal disease, either near or remote.

5. In the treatment of all diarrhœal diseases it should be borne in mind that there is something more to be considered than the bacteria and the products of decomposition, viz., the anatomical changes.

15 EAST FIFTY-FOURTH STREET, NEW YORK.

THE DISORDERS OF MENSTRUATION.[1]

BY ANDREW F. CURRIER, M.D.,
OF NEW YORK.

IT is a peculiarity of the functions of the body that, when performed normally, they are performed painlessly and without the knowledge or consciousness of the individual. When an individual becomes aware that this or that function is being performed —that is, when his attention is attracted with an intensity which he cannot dismiss, his emotions being involved to any degree between simple discomfort and the most diabolical pain—there is no question that one of the functions is deranged, disturbed, disordered.

I do not know whether the argument has ever been made that, since it was once said to woman, "I will greatly multiply thy sorrow and thy conception, in sorrow thou shalt bring forth children," therefore it follows that menstruation should be included in the primal curse. Certainly "parturition hath few pleasures," but it cannot be argued from that fact that menstruation should abound in pain.

It has been asserted by various authorities, more as a matter of personal belief and opinion than as a fact founded upon anatomical or physiological conditions, that menstruation is, or always should be, attended with more or less pain; but, with all deference to such authority, that is not my belief—indeed, if it is normally accomplished, it should be as painless as digestion, or secretion, or assimilation. In this opinion I am in accord with Meadows, who made an elaborate discussion of this question in the Harveian Lectures for 1881 (see *Med. Press and Circular*, xxxii. 487).

Menstruation, in its simplest meaning, signifies a discharge of blood, epithelium, and glandular secretions from the uterus, mingled with more or less of the secretions of the vagina and vulva, recurring each lunar month, continuing from three to six days, due to a stimulus which has not yet been absolutely determined, which produces congestion of the entire genital apparatus, and attended by both direct and reflex phenomena which seem to depend mainly upon the congestion. From this definition as a basis, all the irregularities of menstruation may be wrought out.

There have been much patient work and ingenious speculation in regard to the process which actually occurs with menstruation. The subject was deemed of so much importance that a special discussion of it occupied a portion of the attention of the International Medical Congress held at Paris, in 1867, many valuable papers being read and discussed.

Physiologists and clinicians have alike failed to settle conclusively whether the entire mucous membrane is shed with each recurring menstrual epoch, or only certain epithelial layers (Leopold, John Williams, Möricke, Wyder, and others); whether the menstrual discharge means an aborted decidua (Pouchet, Ercolani, Tarnier, Putnam-Jacobi); what may be the influence and bearing of the Fallopian tubes in the matter (Harley, Tait), and many other important questions, into the merits of which it is not intended to go at this time. Beigel's theory concerning menstruation is that it is due to an im-

[1] Read before the New York State Medical Society, February 6, 1889.

pulse in the genital sphere, an expression of which is sexual excitation, just as there is a regular expression of need for rest, food, etc. Hyperæmia follows, especially in the pelvic organs, and menstruation is the result.

Such a theory is too abstract and vague, and demonstrates nothing. A more reasonable theory is that of Pflüger, which makes menstruation dependent upon the maturation of the ova. As the Graafian follicle swells, vasomotor nervous influences are excited, which become diffused through the vascular system and cause congestion. The congestion involves the ovarian circulation, and contributes to the bursting of the Graafian follicle, the liberation of the ovum, and the consequent hemorrhage. This theory is also unsatisfactory, for it requires that ovulation should be attended by external hemorrhage, and it is not impossible that one may occasionally be entirely distinct from the other. Upon this point Dalton ("Report on the Corpus Luteum," *Trans. Amer. Gyn. Society*, ii. p. 111) remarks: "If we regard the rupture of an ovarian follicle and hemorrhage from the uterus in menstruation as two phenomena normally coincident, excited by a common cause, and both subservient to the same general function, we must still recognize the possibility of either one being deranged independently of the other" (p. 137).

Pouchet, who devoted a considerable portion of his life to the investigation of the subject of menstruation, leaving a magnificent memorial of his work in his *Théorie positive de l'ovulation spontané*, was the first one, so far as I can ascertain, to recognize (1847) the analogy between the mucous membrane which is shed from the uterus of all unimpregnated women, to a greater or less extent, each month —the *decidua menstrualis*, and the decidua which forms an enveloping membrane to the fœtus. Or, perhaps, it is more correct to say that he recognized that a decidua is formed each month, which is cast off if impregnation does not occur. His theory of menstruation, like Pflüger's, is that it is dependent upon ovulation, and that the commotion aroused by the maturation of ovules not only excites the genital apparatus, but reacts upon the whole individual (*Op. cit.*, p. 201).

Goodman opposes the ovular theory (*Trans. Amer. Gyn. Society*, ii. p. 650) on the ground that menstruation is presided over by a law of monthly periodicity, which is the resultant and exponent of recurring physiological acts. This law is manifested only in the economy of the female, and in connection with the function of menstruation. He believes that the process by which the monthly cycles are accomplished is seated in the ganglionic nervous system.

Whatever be the correct theory as to the impulse which causes the periodical ovarian congestion, and coincidently the congestion of the other pelvic organs, the most superficial examination of the ovaries shows a relatively extraordinary system of arteries, which one could hardly conceive, by any possibility, to be necessary for the ordinary nutrition of the organs; and, hence, they could only be designed for repeated fluxions and engorgements. The great plexuses of veins contiguous to the ovaries, in the broad ligaments, testify also of the volume and activity of this portion of the circulation, and the possibilities for its derangement. Together with these facts must also be borne in mind the wonderful nerve supply of the ovaries by the renal, the ovarian, and the superior aortic plexuses. Therefore, given a highly congested and engorged ovary, and direct or indirect nerve communication with the most important structures and organs of the body, we can readily understand why so many women are in such a condition of unstable equilibrium with each recurring menstrual epoch, and why so many disturbances in parts remote from the ovaries are properly referred to them as the *fons et origo*.

The argument has been made that the function of menstruation is one which has been engrafted upon women as a result of civilization (Stirton, *Glasgow Medical Journal*, January, 1887, p. 1). In so far as this implies that under favorable environment, which is a very comprehensive term, women menstruate with less inconvenience, and likewise give birth to more and healthier children than under less favorable environment—that is, in the savage or barbarous condition, it is probably true, just as in stock-raising and breeding the results are much more satisfactory, in every way, when the creatures are well-fed and housed; but we must not forget that man is the end of the scale in evolution, and that the higher intellectual faculties seem to be developed at the expense of the lower animal ones. A fish has myriads of offspring, an elephant perhaps one. Your Shakespeares, and Washingtons, and Newtons, and Napoleons, and Goethes, and Carlyles have not been prolific. So of the George Eliots, the Madame de Staels, and the Elizabeth Brownings. That is to say, the greatest intellectual development in women is not favorable to fecundity, and probably is not favorable to ovulation, though the latter statement remains to be proved. The congestions in such women which preponderate are cerebral rather than pelvic; therefore, civilization in its most complete development may be unfavorable to menstruation. Certainly menstruation is not a flower of *modern* civilization, for in almost all nations and races which have left records of their habits and customs this function is referred to. The Bible record of its existence among the ancient Hebrews is clear and explicit, and it is plain that it was not a rudimentary function then.

Instead of regarding menstruation as an engraftment upon civilization, it would seem more reasonable to consider it as the development and perfection of a function associated with the reproductive system which has been observed with greater or less distinctness in almost every variety of animals the habits of which have been subjected to careful study. The testimony in this direction is most abundant and most convincing. The females of certain insects exhibit decided changes of color during the breeding season. In reptiles and fishes the period in which the eggs are deposited is marked by a certain degree of excitement and by hyperæmia of the orifices of the generative canal. Laycock observed that tortoises exhale an odor of musk, and lizards secrete an odorous, fatty liquid when the sexual appetite is aroused, and Darwin observed that during the breeding season the anal scent-glands of snakes and lizards were in active secretion. (See Wiltshire on "Comparative Physiology of Menstruation," *Journ. Comp. Med. and Surg.*, iv. 28; v. 58, 163, 254.) Among birds the reproductive season is marked by brighter plumage in the female than at other times.

Ascending in the scale, we find not only that the sexual appetite is aroused with something like periodicity, but that it is accompanied with more or less discharge from the generative passages, in which the sanguineous elements increase the higher we advance in the scale. With wild animals the sexual appetite is more intense when food and shelter are sufficient. In some of the domestic animals it recurs with a sanguineous or sanguino-mucous discharge with almost as great regularity as in women, and has been thus observed in mares, asses, ewes, sows, bitches, and cats. With animals having hollow uteri the external hemorrhage is less profuse than in those in which the uteri are thick and nearly solid; therefore, while the transudation into the uteri of bitches, sows, and cats may be abundant, the external hemorrhage may be quite insignificant.

In those primates in which the womb most resembles that organ in woman—that is, in the monkeys—the external hemorrhage is quite similar to that which occurs in woman. This fact has repeatedly been observed in monkeys kept in zoölogical gardens, and the bleeding has sometimes been so profuse as to excite marked concern on the part of their keepers. Buffon mentions eleven varieties of apes, baboons, and monkeys, in which menstruation had been observed. To mention, in addition, the names of Cuvier, Saint-Hilaire, Ehrenberg, and Raciborski as observers of facts similar to the foregoing, is sufficient to show that the subject has received critical attention from the most careful and eminent investigators.

Among wild mammalia the analogue of menstruation was observed by Bartlett, a keeper of the zoölogical gardens in London, in elephants, hippopotami, zebras, jackals, and monkeys. Saint Cyr and Fleming, distinguished veterinarians, have published the results of their observations as to the existence of a sanguinolent œstral discharge in the domestic animals resembling the catamenia in women, and they maintain that though it may not be so invariable, so copious, or so well defined as in women, this fact is often due to its retention in the vagina and its passage outward with the urine. Modern obstetricians and clinicians, including Velpeau, Trousseau, Cazeaux, and Tarnier, have all observed the analogy between menstruation in woman and a periodic flow in other mammalia, especially in monkeys and the domestic animals.

It would, therefore, seem warrantable to conclude with Wiltshire, from whose admirable lectures most of the foregoing facts have been obtained (*op. cit.*), that menstruation agrees with other functions of the animal economy in displaying subordination to the law of evolution. It may be indebted to civilization for certain fostering influences, but it does not originate in civilization but in a law which applies to the reproductive system of vast series of types and forms of animal life.

If this review of the comparative physiology of menstruation has seemed tedious, it is hoped that it may not be valueless as an introduction to the consideration of the abnormalities of the function.

Normal menstruation, then, implies a flow of blood sufficient to relieve congestion—but not enough to cause weakness or exhaustion, unaccompanied with pain, by way of the genital passages. Conversely, abnormal menstruation implies an insufficient flow of blood, or an excessive flow—these terms being relative, for *insufficient* and *excessive* vary greatly with individual condition; or it may mean a flow that is accompanied with pain, or proceeds by other channels than the generative passages.

Disorders of menstruation may, therefore, be classified as follows:

1. Amenorrhœa, absence of the menstrual flow.
2. Dysmenorrhœa, the condition in which the menstrual flow is obstructed.
3. Oligomenorrhœa, scantiness or insufficiency of the menstrual flow.
4. Polymenorrhœa, excessive menstrual flow.
5. Atopomenorrhœa, menstruation or a menstrual flow which is out of place, or unnatural, or unwonted. This term corresponds with the expression vicarious menstruation, and its equivalents, ectopic menstruation (Barnes), ataxie menstruelle (Raciborski), xénoménie (Flamant).

The terms metrorrhagia and menorrhagia have been used to signify, respectively, excessive bleeding from the womb irrespective of menstruation, and excessive menstrual flow. I have introduced the

term polymenorrhœa as a substitute for menorrhagia.

The classification which has heretofore been in use, is that which was adopted by Henry Bennett (see *Lancet*, 1852, i. 35, 65, 215, 328, 353) and others, and seems to me to be deficient in definiteness.

Inasmuch as menstruation is influenced to so great a degree by such conditions as race peculiarities, nervous impulses, blood-pressure, heart force, and resisting power of vascular walls—internally, and atmospheric pressure, humidity, heat, cold, and wind currents (that is, by meteorological elements)—externally; we can readily understand why its equilibrium should be so unstable—indeed, there is probably no function that is so delicately poised, which accounts for the fact that we see so many illustrations of menstrual disorders and disturbances.

Certain general principles are usually admitted by those who have investigated this subject, and among them are the following:

1. Races or tribes that are least removed from animals most resemble animals in respect to this function. Thus Stirton (*Glasgow Med. Journ.*, 1887, p. 1) mentions an aboriginal and very degraded tribe in South Africa, of which the women menstruate only at irregular periods. When menstruation is first established the discharge is merely an abundant mucous secretion, and only after indiscriminate intercourse has taken place for some time, does blood appear with the menses, and then only in small quantities.

2. So-called nervous women, or women whose nerves are very readily stimulated or excited, seldom menstruate without discomfort. Such women frequently suffer from dysmenorrhœa, many from oligomenorrhœa. A sudden emotion of joy, fear, or sorrow may check their flow; or it may be brought on prematurely or profusely by lascivious thoughts.

3. Influences located in the vascular system may, in themselves, be sufficient to determine great abnormalities in menstruation. A weak heart forces too little blood into the pelvic channels, the blood-pressure is slight, and the hemorrhage is correspondingly small. Or the heart works violently; as the time for menstruation recurs there is high blood-pressure with abundant power to overcome the resistance of the vascular walls, and the hemorrhage is profuse.

4. Great elevations, in which the atmospheric pressure is greatly reduced, must favor profuse menstruation as the pressure in the engorged pelvic vessels becomes greater than the external pressure. This remark applies more particularly to sudden removals to and short residence in such localities, for acclimation may be readily acquired if no serious disease involving the vascular system exists—in fact, in certain mountainous districts of France and Switzerland it has been observed that the native women are prone to suffer from irregular and scanty menstruation, notwithstanding the low atmospheric pressure.

5. A humid atmosphere is frequently a concomitant and probably a cause of amenorrhœa, or dysmenorrhœa, or oligomenorrhœa, on account of the difference between the pressure of the gases and fluids within the body and the atmospheric pressure. These conditions are frequently observed in women who are about to menstruate at a time when the air is nearly saturated with moisture, also among those who sojourn by the seashore during the summer months, and in connection with ocean voyages. In New York City and probably in any great port of entry, one sees many immigrant women with whom amenorrhœa persists for months after their passage across the Atlantic. It is usually the young and unmarried who are thus affected, and the condition assumes great practical importance from the fact that one is obliged to determine as to the presence or absence of pregnancy.

6. In hot climates women menstruate earlier than in cold. It is not unusual for puberty to be attained between the ages of eight and twelve years in tropical countries, and the well-authenticated stories of precocious maternity which are not uncommon in India, and other countries of that latitude, show the great influence which heat exerts in developing and maturing animal as well as vegetable life. Rouvier, in an excellent statistical paper concerning menstruation among the heterogeneous population of Syria (see *Ann. de Gyn.*, 1887, xxvii. p. 178), states that among 742 cases of women of ten Oriental nationalities seen by him in a professional capacity in the city of Beyruth, the average age at the first menstruation was twelve years and ten months. The youngest menstruated for the first time at the age of nine and the oldest at nineteen. Among the Bedouins he found that menstruation began at the age of eleven. Menstrual life, according to Wiltshire (*op. cit.*), is usually begun in the summer-time, and the same author thinks that the seasonal influence underlies the genesial influence in all creatures, and is a trace of a primordial condition governing reproduction. Heat is also an influence which tends to shorten the menstrual life. It is said that some of the Arab women cease menstruating between the ages of twenty and thirty (see *Real Encyclopædie*, article "Menstruation").

Cold—that is, extreme cold—is an agent which at all times and in all latitudes is unfavorable to the regular and easy performance of the menstrual function. As one travels toward cold climates the establishment of the function seems to be proportionally retarded. In northern European countries it is

not at all uncommon for females to menstruate for the first time at the age of seventeen or eighteen, as the statistics of Leudet's table show. This was published in the *Transactions of the International Medical Congress* held at Paris in 1867 (p. 162) and the following are some of its important statements:

Average age for the establishment of menstruation from a large number of observations in:

	Years.	Months.
Swedish Laponia	18	
Copenhagen	18	9
Norway	16 to 18	
Göttingen	16	
Stockholm	15	6
England	15	6
Bombay	13	
Calcutta	$12\frac{4}{10}$	

Heinricius examined the histories of 3500 women of the working class in Finland, and found that in that cold country the average age for the first menstruation was fifteen years, nine months and twenty-five days (*Centr. f. Gyn.*, 1883, vii. 72).

It is thus an unquestionable fact which entirely controverts the opinion of Bennett (*op. cit.*) and others, that the influence of climate upon the menstrual function has not been exaggerated. Hennig is responsible for the statement (see *Centr. f. Gyn.*, 1887, No. 17, p. 274) that the Greenlanders and Laps menstruate only once in three months, and the Eskimos not at all in winter; also, that the women of Terra del Fuego do not menstruate at all or only infrequently during the winter. The effect of cold in suddenly checking the menstrual flow, illustrations of which are common enough among washerwomen and others who intentionally or unintentionally disregard the proper precautions against disturbance of the menstrual flow, is well known; and the subsequent pain and annoyance which frequently result, are equally familiar, and furnish an instructive commentary upon the fact that nature imperiously demands compliance with her laws, ignorance not being a valid excuse for their violation.

Returning again to the classification which was proposed, disorders of menstruation are to be considered as:

1. Amenorrhœa (ἀ not, μῆνος monthly, ῥεῖν to flow).
2. Dysmenorrhœa (δύς bad or difficult, μῆνος monthly, ῥεῖν to flow).
3. Oligomenorrhœa (ὀλίγον a little, slightly, μῆνος monthly, ῥεῖν to flow).
4. Polymenorrhœa (πολύ much, abundantly, μῆνος monthly, ῥεῖν to flow).
5. Atopomenorrhœa (ἄτοπον out of place, unwonted, μῆνος monthly, ῥεῖν to flow).

I. *Amenorrhœa* means absence or disappearance of the menstrual flow. This condition obtains with those who have passed the menopause, whether in the ordinary course of nature, or as a result of disease or traumatism. In some cases, no valid cause for its existence is discoverable. The term is not strictly applicable to those with whom the menstrual secretion is retained within the pelvic organs on account of obstruction of various kinds. It may be temporary or intermittent, as in the case of those who dwell in a very humid atmosphere, or in very cold climates, in connection with the pregnant state, in wasting diseases, etc.

The question has often been raised, whether amenorrhœa has any significance or influence upon the general health. In my opinion, its influence in this direction may be decided, but I am familiar with cases in which it has existed for periods of five to seven months, in which the cause could not be ascertained, the patients enjoying the best of health during these periods, and showing no substitute for menstruation by abnormal bleedings or other phenomena. Such patients usually consult the physician under the superstition that continued absence of the menstrual flow may be an indication of approaching pulmonary phthisis. One hundred and fifty years ago this question was elaborately discussed by Senfft, in a Latin treatise published at Leipzig. (An fœmina sine catameniorum fluxu perfecta frui possit sanitate, Lipsiæ, 1740.)

Whether menstruation coincides invariably with ovulation is at present immaterial, though we know from the vast experience which has accumulated since the era of abdominal surgery began, that with the removal of the ovaries menstruation ceases in the majority of cases after a short period. It seems evident that the monthly flow is the medium by which the recurring congestion of the pelvic organs is relieved, whether directly associated with the discharge of an ovum or not. If the congestion does not recur, whatever be the cause, amenorrhœa is insignificant; if it does recur, it must follow the law which governs congestion in other parts, and unless relieved by the emission or dispersion of the blood, trouble must invariably result. Such trouble will be indicated by a sense of pain and fulness in the pelvic region; by pain in the loins from involvement of the renal plexus of nerves; and by pain in the head from communication with cerebral nerves and centres. That such communication exists, is demonstrable by the pain in the head, especially in the occipital region, which is frequently elicited by the pressure of the examining finger upon inflamed circumuterine tissues.

Amenorrhœa is not usually annoying to those who suffer from pulmonary phthisis and other wasting diseases. Dalton has reported cases in which it existed in young women for many months before death as the accompaniment of disease of the liver, kidneys, or heart. It is usually troublesome in

young women with whom menstruation is not fully established, and in those cases in which there is mechanical obstruction of any kind to the passage outward of the blood from the vessels. Not infrequently atopomenorrhœa results if mechanical obstacles to the normal outflow are present.

II. *Dysmenorrhœa.* This term, as it is commonly used, is the least exact of any of the terms in the proposed series. It is almost invariably associated in the mind of the physician with pain, and yet, there are doubtless many cases in which there is difficulty in relieving the engorged vessels during menstruation, true dysmenorrhœa, in which there is little, if any, pain. The term includes those cases in which, though there is a flow of blood, the blood is ejected or emitted with difficulty. In its broadest sense, dysmenorrhœa is the condition which is opposed to normal menstruation. and in that sense it includes all the disorders of menstruation. The causes of the difficulty may be mechanical or chemical—that is, the fault may either be in the blood or in its surroundings, and pain is not infrequently a symptom or announcement of the condition. The pain may be referred to the region of the uterus and be of a grinding, bearing-down character; it may be in the loins, in the back of the neck, in the head, etc. There may be a general feeling of discomfort with soreness of the muscles and joints; there may be nausea and vomiting; and there may even be violent mental agitation. The influence of the nervous system in this condition is profound. Phlegmatic women seldom suffer from any of the foregoing symptoms during menstruation, unless there are serious mechanical obstructions to the outflow of the blood. On the other hand, sensitive and hysterical women are almost always dysmenorrhœacs.

We hide our ignorance of the occult anatomical lesions which exist in these cases, by saying that the phenomena are the result of temperament. The truth probably is, that there is no complaint or disorder from which organized beings suffer, whether in great or small degree, which has not its correspondent molecular derangement somewhere, though it may be beyond the power of demonstration by mind and microscope. The mechanical causes of dysmenorrhœa are far more common than the chemical—in fact, it is difficult to conceive of dysmenorrhœa in which the mechanical element plays no part.

In the weak and flabby uteri of young women with poor nutrition and over-stimulated brains we find dysmenorrhœa associated with deficient arterial tension. There is insufficient force to expel the blood through the distended veins and capillaries, or the uterus with its weak and imperfectly nourished muscle contracts too feebly upon the exuded blood to force it out of the uterine cavity. Similar difficulties in the vascular apparatus obtain in the heavy and boggy uteri of subinvolution. In anterior and posterior displacements the blood may be confined in the uterine cavity, and the force of contraction be spent at mechanical disadvantage in removing it. In certain forms of intra-uterine tumors similar accumulations and inefficient contractions may also exist and dysmenorrhœa with its attendant phenomena result. Obstruction may also be caused by hypertrophied mucous membrane constituting the so-called membranous dysmenorrhœa.

Again, dysmenorrhœa may arise in connection with various atmospheric conditions, such as have been enumerated in a preceding paragraph. The chemical condition of the blood may also be such as to prevent free transudation from the vessels during menstruation. Theoretically, an excess of the albuminous or fatty constituents with imperfect assimilation, a superabundance of corpuscles with corresponding deficiency of water and high specific gravity, may all act as sufficient causes of dysmenorrhœa. The same may be said of blood in which large quantities of sugar, pigment, parasites, and other foreign matters are circulating. In all such conditions, we should have a circulating fluid with increased specific gravity, and in so far as menstruation is dependent upon osmosis the fluid would transude with more than ordinary difficulty. I admit that this is entirely theoretical and know of no investigations which have been made upon the subject, but it seems to be in accordance with physical laws. Dysmenorrhœa, therefore, is not a single symptom but a complex of symptoms. It is not a disease as that term is ordinarily understood, though it is a morbid condition.

III. *Oligomenorrhœa.* The condition in which the monthly flow of blood is too scanty to relieve the pelvic congestion is very frequently associated with dysmenorrhœa, and in such cases presents more or fewer of the symptoms which are common to that condition. The term is relative, for the loss of a few drachms of blood in some individuals is all that seems necessary to restore the normal tension to the pelvic vessels. With such persons there may be no symptoms of dysmenorrhœa, and while they may enjoy a fair degree of health they are more frequently women with phthisis or anæmia, or some other constitutional vice.

Oligomenorrhœa sometimes persists during the pregnant state, recurring at that time in the month when the ordinary menstrual flow was wont to appear. It may occur in connection with deformities or want of development of the uterus or ovaries, or during the latter portion of menstrual life, and in such cases may be unaccompanied with dysmenorrhœa. Oligomenorrhœa with dysmenorrhœa is frequently present in cases which offer decided mechanical obstruction to the menstrual flow, as in cases of exaggerated anteflexion, and less frequently in cases of marked

retroflexion. It is frequently present in women who are very fat, whether the latter condition be one which has persisted from childhood, or has occurred, as is frequently the case, as the consequence or result of numerous pregnancies in rapid succession. In the oligomenorrhœa of anæmic women, the blood contains comparatively few corpuscles and is mostly serum. It serves as a fair index of the character of the blood which is circulating in the patient.

IV. *Polymenorrhœa.* This is also a term which must vary in its significance with the individual. I have seen women who bled profusely for days and weeks, some days losing at least a pint of blood, and yet preserving a ruddy complexion and a fair degree of strength. The losses of blood which are frequently sustained in connection with uterine cancer, polypi, and other neoplasms, before the evidences of the drain upon the resources appear upon the skin, or in the waning powers of endurance, are sometimes almost incredible. Polymenorrhœa is also a very common occurrence as the menopause approaches. At such times it is frequently associated with developing malignant disease, and in certain quarters, both lay and professional, the latter is looked upon as a necessary accompaniment of the menopause, hence it is termed "the critical time." It is critical simply in individual cases, not because it is nature's method to terminate the history of a function with a series of bloody inundations; it is no more critical than any other period of menstrual life, unless there is a foundation of disease which can be favored and encouraged by the changes in tissue vitality which characterize the approach of old age.

Again, every gynecologist sees plenty of weak and anæmic women who give no history of losses of large quantities of blood, and yet the loss of a few ounces with each recurring period brings them to the verge of collapse. Such cases require active treatment quite as much as those in which the quantity lost is far greater. The blood-making powers of the latter are far more active than those of the former. It may generally be assumed that a menstrual period which continues longer than a week, has abnormal conditions associated with it, and should be stopped. This is especially true if the flow has been profuse, and though the patient may for a time see nothing in her condition to disturb her, with the exception of the annoyance which attends frequent and protracted bleedings, her vitality will eventually be sapped by the continuance of such a condition, and hence the sooner its cause is discovered and remedied, the better. Those who bleed for long periods of time, at regular menstrual intervals, will sooner or later be bleeding at irregular intervals unless relieved, and it is the part of wisdom and conservatism to investigate in all cases, as soon as possible, after the polymenorrhæa has been established.

One of the most common causes of this condition is carcinoma. For a long time the bleeding may not be due to sloughing and rupture of vessels connected immediately with the disease, but to the increased uterine congestion which attends its development. Other malignant diseases of the uterus produce excessive bleeding in the same manner as carcinoma—that is, by increasing to a very great degree the volume of blood which is directed to the organ; but they are far less common than carcinoma. Benign growths occupying the interior of the uterus, or imbedded in its muscular structure, are almost always a cause of polymenorrhœa, especially if near the trunk or main branches of the uterine artery, and it is perfectly intelligible that this should be the case.

Various diseases of the lining mucous membrane of the uterus, apart from the malignant diseases, are prolific sources of polymenorrhœa. Modern surgical gynecology has done much to relieve such conditions which were once as fatal as cancer, and with the imperfect methods of examination formerly in vogue were probably diagnosticated as cancer.

There are also certain occupations which seem to favor excessive bleeding at the menstrual period, and we may be unable to find any evidence of disease in the uterus or its surroundings in those who are thus suffering. Occupations in which the individual is constantly exposed to a very high temperature have this tendency, and I have seen a number of cases among cooks and laundresses. Among prostitutes and others who have greatly abused the sexual act, polymenorrhœa is also of frequent occurrence.

When we think of the great progress which has been made in recent years in the diagnosis of so many conditions which have excessive uterine hemorrhage as the chief symptom, and the means which have been devised for their effectual relief, there is cause for profound gratitude.

V. *Atopomenorrhœa.* This term includes every variety of monthly flow, or substitute for the monthly flow by any other channel than the one which nature designed for that purpose. The term *vicarious* menstruation is a very awkward one, and properly means the menstruation which one person suffers or experiences for another. This is, of course, an absurdity, and only by twisting the term from its proper significance can it be understood as referring to menstruation which occurs through abnormal channels. The term xenomenia, which was proposed by Flamant, in 1720, is a good one, and is etymologically correct, but for the purpose of uniformity perhaps the more clumsy term which I have suggested would be preferable.

A common form of atopomenorrhœa is the bleeding from the nose which occurs with young girls during the first few months of puberty. It usually

requires no treatment, and may be considered as a means of relief to a congestion which is displaced. Bleeding from the anus, especially in those who suffer from hemorrhoids, is another form of this condition, which is perfectly intelligible, and may usually be relieved by the destruction of the enlarged veins. Other abnormal bleedings which may occur with the normal menstrual flow or in the absence of it, are bleedings from the lungs or stomach; bleedings into or through the skin or mucous membrane in the form of purpura and various extravasations and transudations; bleeding in connection with acne, nævi, ulcers, and fistula; bleedings from the gums, the nipple, the anterior chamber of the eye, the external auditory meatus, and other places.

The foregoing facts seem to prove that the monthly congestion in women, whatever be its cause, is not local, but general; or, at any rate, that the vascular tension at such times is raised, so that veins and capillaries which are near the surface are much more liable to rupture than under the ordinary conditions of tension and pressure.

159 EAST THIRTY-SEVENTH STREET.

IDIOPATHIC ACUTE PAROTITIS; SLOUGHING OF THE ENTIRE GLAND; RECOVERY.

BY RICHARD H. DAY, M.D.,
OF BATON ROUGE, LA.; EX-PRESIDENT OF THE LOUISIANA STATE MEDICAL SOCIETY,

THERE is but little said in our standard authors, or in the current periodical medical literature of the day, on parotitis; and what little is said, applies more especially to its occurrence in its specific character, under its common form of mumps.

Bryant, in his *System of Surgery*, treats of it simply in its specific form, but says, "when it follows upon a fever, it is a severe affection, and not unfrequently passes on to suppuration; such abscesses spread easily, the deep fascia covering them in, forbidding a natural outlet except by burrowing."

Wythe in his recent text-book on surgery, in a few lines only, writes of it as parotitis, or mumps, but adds: "abscess may occur after an acute inflammation of the parotid from traumatism, or as a complication of the eruptive or continued fevers. Under these last conditions, the prognosis is always grave."

Gross, in his comprehensive work on surgery, is much more full and clear, and I must be allowed to make a rather lengthy abstract, from the work of this great author, since it conveys more information upon this grave form of parotitis, than is to be derived from any other source. He says:

"Abscess of the parotid is nearly always of an acute character; being usually a result of simple inflammation, local injury, erysipelas, typhoid fever, smallpox and other eruptive diseases. Sometimes the swelling is remarkably diffused. The fluctuation is generally very obscure on account of the manner in which the contents of the abscess are bound down by the cervical fascia and the capsule of the gland. Owing to this circumstance, the true nature of the disease is apt to be overlooked, and the pus allowed to burrow about in different directions; thus producing the most serious mischief, opening, perhaps, after having induced the most violent suffering, into the auditory tube, or extending down the neck along the great vessels, and causing extensive havoc in the connecting cellular tissue. In some instances the fluid passes round the trachea, and finally destroys life by bursting into the chest.

"*Gangrene.*—Mortification of this gland occurs chiefly in erysipelas, typhoid fever, scarlatina and smallpox. Fortunately, however, it is very rare in any form of the disease. The sloughing is usually most extensive in the connecting cellular tissue, but occasionally it affects the glandular substance also, which it may completely destroy, as I have had occasion to observe in several cases. In one of these not a vestige of the organ was left, its former site presenting a deep hollow extending down to the ramus of the jaw and the auditory tube."

It is thus seen that however simple and unimportant specific parotitis may be, and is, as it is usually observed; when it occurs as the sequel of the eruptive or continued fevers, or of pyæmia, as in the case of the lamented Garfield, it may become a disease of the gravest character, and develop the most serious consequences.

The case that I have now to report differs in its etiology from any of the cases spoken of by these authors in that it was not a sequence of any eruptive or continued fever, nor the result of pyæmic poison, neither was it specific in character; but, as will be seen, was an acute idiopathic inflammation of the parotid gland; autogenetic in origin and resulting in the complete and entire sloughing of the gland. As such, I report it as a complement to the meagre and incomplete history and literature of acute parotitis.

The subject in whom it occurred was K. P., a mulattress, aged about thirty-two years, a native of Baton Rouge, La. She is the mother of two children; the elder if living, would now be about sixteen years old, having died in 1878, when five years of age—cause of death continued fever, resulting in inflammation and ulceration of the right side of the face, and terminating in gangrene of the soft parts and necrosis of the maxillary bones. The younger child is now seven or eight years old, and appears to be in the enjoyment of good health. I have known this woman, since her childhood. She is tall and spare, and has always been delicate. She is thin in chest, and is of a strumous or scrofulous diathesis.

On this occasion I was called to see her on August 23, 1888, and finding her under the treatment of another physician, I withdrew, making no examination into her condition.

On the 25th I got a note from her doctor request-

ing me to see the case with him. I found the left parotid very much swollen, very hard, and exquisitely painful; and the whole integuments on the left side from the chin, back to the mastoid and down to the clavicle, diffusely inflamed, and so extremely sensitive that the softest touch produced the most excruciating pain. The pulse was small, frequent, and feeble, and accompanied with great systemic prostration. I advised the application of a hot flaxseed poultice over the gland and inflamed integuments; chloral and morphine to ease pain and procure sleep; a liquid nutritious diet, and enemata as might be required to move the bowels, and five grains of quinine to be given three times a day.

On the 13th of September I was again sent for, and requested to take charge of the case, the attending physician consenting and relinquishing all further control. I found the patient much exhausted and reduced in flesh from constant excruciating pain and inability and disinclination to take food. The gland and integuments were still inflamed and more distended and painful, with obscure fluctuation at two points (*a*) at the upper edge of the gland and (*b*) below the angle of the jaw. The doctor preceding me had supposed the case to be abscess in the mastoid cells, and had made a free cut down upon that process, but without finding any pus. I made a free incision at the two points designated; from the upper one, I suppose about a tablespoonful of ill-looking thin pus escaped; from the lower opening, only a little thin sanious fluid exuded.

These incisions into the parotid revealed the fact that the entire gland was in a sloughing process, that it was necrosed, and undergoing disorganization. I could with gentle force pass a silver probe in different directions through the gland, causing not as much pain as was induced by touching the investing integuments.

My course was a plain one. Support the patient's strength, quiet pain, disinfect, and promote as fast as possible the sloughing and separation of the necrosed gland. To accomplish the first indication, I insisted upon the regular and frequent administration of cow's milk, beef broth, Ducro's elixir and port wine, and small doses of quinine three times daily; for the second, fifteen grains choral with one-quarter grain morphine were given as needed, both to ease pain and to procure sleep at night; and for the third indication, I used a flaxseed and charcoal poultice applied warm and made fresh three times a day, and injected into the upper opening a weak solution of carbolized oil at each dressing.

I was assisted by a good nurse, who carried out my instructions faithfully; and every alternate day I made a visit and removed with forceps and scissors such portions of the gland as I could draw through the opening, and that were manifestly dead.

On the 20th of September I lifted out through the upper opening the entire remnant of the gland in a coherent mass, which had been completely detached by the *vis medicatrix naturæ*, leaving a deep sulcus, or hollow, extending down to the underlying bloodvessels. This cavity I had syringed out daily with a weak solution of carbolized oil, and applied over the integuments a thick pad of carbolized absorbent cotton and oakum, so as to press the surfaces together, to exclude the ingress of air and facilitate granulation. The dietetic treatment was continued, and the chloral and morphine were dispensed with. In addition, I now put my patient upon cod-liver oil, which I found of great benefit. The cavity gradually closed and healed over, the patient in the meantime improving in flesh and strength, and finally was restored to her customary health; leaving however, a deep and marked depression in the site of the missing parotid.

I look upon this case as not without interest to the medical profession: 1st. In its unmistakable autogenetic origin; 2d. In the entire and complete sloughing away of the gland by a gangrenous process, a very rare occurrence; and 3d. In the final good result of the case, and the restoration of the patient to her former, if not even better, health.

MEDICAL PROGRESS.

The Treatment of Diphtheria with a Spray of Hydronaphthol, Papain, and Hydrochloric Acid.—Dr. W. C. Caldwell, of Chicago, assumes:

1. That diphtheria, at first like wound and puerperal sepsis, is a local disease, and that the temperature is due to the absorption of leucomaines. It is probable that later the microbe of septicæmia, and possibly the microbe of diphtheria, may enter the blood and produce a general disease, the temperature being due in part to the leucomaines produced by the microbes which are multiplying in the blood and lymph

2. It is probable that the pseudo-membrane is over the site of local primary infection, and that in it and specially beneath it in the lymph spaces of the submucous tissue are the invading bacteria of diphtheria.

Hence, if diphtheria is at first a local disease, and later may become a general disease, either a septicæmia or diphtheræmia; and if this local infection is accompanied by a pseudo-membrane which covers over the invading bacteria, the indications for treatment are the prompt, frequent, and effective application of remedial agents which will—

First. Remove the pseudo-membrane, so that the bacteria can be reached; and,

Second. Arrest the growth of the bacteria.

For convenience, the author prescribes these drugs in the same mixture; but it should be remembered that they must not neutralize each other's actions, or in any way be incompatible. An antiseptic and peptonizing agent might act powerfully when used separately, but might be inactive when in the same mixture. Pancreatin is an active peptonizer, but it can only be used with an antiseptic which can act in an alkaline menstruum; hence, it cannot be used with bichloride of mercury. Dr. Caldwell has not tried pepsin in combination with an antiseptic. Papaïn acts in an acid, neutral, or alkaline menstrua, and hence it is more available for combination. Bichloride of mercury is a powerful antiseptic in neutral and acid menstrua, but it not only arrests the growth of the bacteria, but also, to a certain extent, the peptonizing ferment. At least it has this effect in artificial digestion; however, the author used it with papaïn

in one case of diphtheria for twenty-four hours. The pseudo-membrane was readily dissolved, and the temperature fell from 103° to 99° from 9 A.M. to 6 P.M. But there is another and far more serious objection to bichloride of mercury, and that is the danger of mercurial poisoning.

Hydronaphthol is also a powerful antiseptic which acts in either a neutral or acid menstrua, and, besides, is not poisonous. No experiments on artificial digestion in the presence of hydronaphthol were made; however, when used with papaïn to spray the throat in diphtheria the membrane rapidly dissolved.

The treatment of the seven cases consisted of—

1. Keeping the bowels open.

2. Ingestion of two to six ounces of milk every two hours. The papaïn probably greatly aids the digestion of the milk, for most of it is swallowed.

3. Spraying the throat every half hour till the temperature is reduced and breathing is easy; then every hour, unless asleep. In these cases, when the spray was used thoroughly, the temperature fell in from four to eight hours. It is probable that the temperature was due to leucomaines only, and that had the treatment been delayed till there was general infection the spraying would would have had much less effect on it.

The following is the prescription for the spray used in these seven cases:

℞.—Papaïn	. . . . .	ʒij.
Hydronaphthol	. . . .	gr. iij.
Acidi hydrochlorici dil.	. . .	gtt. xv.
Aq. destil.	. . . .	ad. ℥iv.—M.

It is no easy matter to apply the spray properly—that is, to the site of infection. It requires three persons to spray the throat effectively, especially when the larynx is involved. One person firmly holds the child in a semiprone position; another depresses the posterior portion of the tongue, rendering accessible the structures involved, both by lowering the tongue and raising the larynx; and the third uses the hand-atomizer rapidly for a few seconds. The child is then given a little rest, and this procedure is repeated several times.—*Archives of Pediatrics*, February, 1889.

Glycerine Suppositories.—DR. SCHAFFER substitutes for glycerine-injections glycerine suppositories made from the ordinary glycerine soap. This soap contains from 20 to 35 per cent. of glycerine, and the suppositories made therefrom have, according to his experience, answered all requirements.—*Münchener med. Wochenschrift*, January 15, 1889.

Liniment for Nephritic Colic.—

℞.—Chloroform	. . . .	15 parts.
Extract of hyoscyamus	. .	15 "
Laudanum (Sydenham)	.	5 "
Oil of chamomile	. . .	150 " —M.

Rub well over the seat of pain.—*L'Union Médicale*, January 24, 1889.

Suppurating Hydatid of the Abdomen Treated during Pregnancy.—In the *Australian Med. Journal* of last month, Mr. Girdlestone records an interesting case of hydatid cyst of the abdomen which required treatment during pregnancy. The patient, aged thirty, had noticed swelling of the abdomen nine months previously, or two months after the birth of her last child. This swelling had been tapped four times. The diagnosis of hydatid was confirmed by the character of the fluid withdrawn; but on admission her temperature and symptoms pointed to suppuration of the cyst. A rounded tumor could be felt in the abdomen projecting against the anterior wall, its upper limit reaching above the umbilicus; it was slightly movable. Mr. Girdlestone passed three long steel acupressure pins, and inserted each of them deeply through the abdominal wall, then through the front of the cyst, bringing the points out through the skin on the opposite side of the tumor; the pins were parallel to each other and three-quarters of an inch apart. Some silk ligature was then twisted round them in the form of the figure 8 over the skin, so as to retain the cyst in contact with the peritoneal lining of the abdomen with a moderate amount of pressure. On the following day the silk ligature was divided, the centre pin withdrawn, and the cyst opened by an incision which extended between the remaining pins. The wall of the cyst was then attached to the skin by four interrupted wire sutures, and the contents evacuated. A large drainage tube was inserted, and retained by fastening it to the wire sutures; the remaining pins were now removed. The cyst was washed out with perchloride solution and dressed antiseptically with iodoform. Recovery was uninterrupted; the wire sutures were removed at the end of a week, and the cavity gradually closed. The operator was led to employ the long pins in order to procure more certain adhesion of the cyst to the abdominal wall, having had a case of somewhat similar kind in which, from some unexplained cause, the cyst became detached at the end of three weeks and the patient died of peritonitis. Another advantage claimed is the possibility of using the scalpel instead of the trocar, thus giving free exit to the contents of the cyst.—*Lancet*, Jan. 26, 1889.

Milk in Infant Feeding.—DR. T. M. ROTCH states (*Boston Med. and Surg. Journ.*, Feb. 7, 1889) that his own belief has long been, that practically for the successful feeding of the young infant with cow's milk (so far as the coagulum is concerned) it is quite as, if not more, important to consider that the total amount of these nitrogenous matters being two to four times as great in cow's milk as in human milk, it is more practical to dilute these matters in cow's milk until the dilution corresponds to that found in human milk, and that then the coagulum will be found to correspond very closely to that of human milk, and will not require to be broken up. An instance which seems to show that this reasoning is practical has recently came to his notice. It is often stated that the curd of human milk is small, soft, and easily broken up, while that of cow's milk is large, tough, and tenacious, so that we should add something to the latter to make the curd fine and friable. These characteristics of the two curds I have found to be present where the milk is in a comparatively normal condition as to the percentage of its albuminoids.

When, however, the percentage of albuminoids in human milk reaches that which exists in cow's milk, we find a curd with the characteristics of cow's rather than human milk, as he found exemplified in the following instance referred to above. An infant seven days old,

and unusually vigorous and well developed, was provided with the milk of a healthy wet-nurse, who had been accustomed to plain but good food. An analysis of the milk made just before it was given to the infant showed the albuminoid percentage to be 2.53 and the water 89.78. The milk was digested perfectly, and the infant throve for the following three weeks. During these weeks, however, the diet of the nurse was changed from the plain food to which she was accustomed, to a much greater variety and amount, and to very rich milk, her usual exercise also being lessened. The infant then began to vomit thick curds identical in appearance and toughness with the curds of cow's milk. An analysis of the milk was then again made, and the albuminoids found to show the high percenage of 4.61 and the water to be 83.50. The nurse was then fed on plainer food and skimmed milk, and the infant soon ceased to vomit. A third analysis of the milk now showed the albuminoids to be decreased again to 2.9.

Dr. Rotch concludes that until something more definite is known concerning this rather theoretical method of treating the albuminoids of milk, that dilution with plain water is the most practical and efficient means at our command.

Menstruation a Contraindication for the Administration of Antipyrin.—DR. H. HUCHARD reports in the *Revue Générale de Clinique et de Thérapeutique*, Jan. 24, 1889. the following case: A few months ago he administered to a woman suffering from severe dysmenorrhœa fifteen grains of antipyrin. After a short time the menstrual flow ceased, the patient being taken with a severe chill, with chattering of her teeth, and the extremities and face becoming cold and cyanotic with repeated fainting fits and syncope. Soon the face became red and flushed the pulse small and soft, the patient complained of severe headache. She recovered. The author observed several other cases with less severe symptoms and has since then not administered antipyrin during the first two or three days of the catamenial epoch.

Perforation of the Vermiform Appendix; Laparotomy; Recovery.—DR. ARTHUR M. JACOBUS reports a case of this and concludes his study of the subject with the following summary:

1st. That typhlitic diseases are intra-peritoneal; that in nearly every instance they originate in inflammation or perforation of the appendix or cæcum, usually caused by fecal impaction or foreign bodies; that even though these diseases frequently do not primarily end in suppuration, still their tendency is to recur and eventually end fatally by septicæmia, or shock from ruptured abscess, or purulent peritonitis.

2d. That, in view of the foregoing, all diseases of this region giving symptoms of inflammation or peritonitis, without regard to the question of pus or abscess, and which do not yield promptly to the modern medicinal treatment and are progressive, should be treated by laparotomy at the earliest period possible.

3d. That when peritoneal or intestinal adhesions or pus-sacs exist, they should always be broken up, the abdominal cavity thoroughly douched with sterilized plain water, at a temperature of 105° F., the wounds sutured, and the cavity drained by glass tubes.

4th. That, excepting in undoubted cases of simple post-cæcal abscess unaccompanied by peritonitis, the incision should be made either vertically over the caput colli (after Sands), or, in the linea alba, below the umbilicus, and preferably the latter operation when extensive peritonitis or adhesions are suspected.

5th. That, whether in operative cases or not, opiates should be used as little as possible; but, on the other hand, saline or vegetable cathartics (followed by enemata) should be used from time to time, to relieve the inflammation, tympanites, pain, and fever, and particularly to drain the peritoneal cavity of serous or purulent effusion.—*Medical Record*, February 2, 1889.

Treatment of Nasal Affections.—DR. COZZOLINO, of Naples, recommends for the various affections of the nasal passages the following compounds:

For scrofulous rhinitis:

℞.—Sulpho-carbolate of zinc . . grs. v.
Salicylate of bismuth . . grs. lx.
Iodol . . . . . grs. vl.
Tannate of zinc . . . . grs. xxx.
Powdered talc . . . . grs. cl.—M.
Use as a snuff.

Chronic catarrhal rhinitis.

℞.—Powdered alum, Borax } . . . 30 grs.
Menthol . . . . . 3 "
Tannate of zinc, Tannate of bismuth } . . . 45 "
Lycopodium . . . . ʒij.—M.

or

℞.—Salicylate of zinc, Tannate of bismuth } . . āā ʒj
Powdered borax . . . 30 grs.
Salol . . . . . 23 "
Powdered talc . . . . ʒij.—M.

Simple acute catarrhal rhinitis.

℞.—Chloride of ammonium . . grs. 45.
Salicylate of sodium . . . grs. 30.
Chloride of potassium . . grs. 45.—M.
To be used as a snuff.

Hyperæmic swelling of the nasal mucous membrane.
A frequent cause of reflex disturbances.

℞.—Glycerin, Water } . . . . āā ʒiv.
Alcohol (rectified) . . . ʒiss.
Menthol, Cocaine } . . . . āā grs. 3.—M.
Use three to four times daily.

Very acute coryza.

℞.—Water, Alcohol (rectified) } . . ʒiv.
Carbolic acid . . . . ʒss.
Menthol . . . . . grs. iv.
Salammoniac . . . grs. 23 to 30.—M.
Inhale.

Powders are best adapted to treating the nasal passages, as they remain longest in contact with the mucous membrane.

For epistaxis, the best new surgical remedy is the hot douche of 122° to 140° F.—*Bull. Médical*, and *Deutsche med. Wochenschrift*, Jan. 24, 1889.

Myrtol as a Disinfectant of the Respiratory Passages.—DR. EICHHORST, (*Ther. Monatshefte*, January, 1889) recommends myrtol as a disinfectant of the respiratory passages.

Myrtol is a clear fluid, has a refreshing odor, and is that portion of the myrtol oil which melts at 158° to 170° Fah.

It is best administered in capsules containing 2½ grains each, of which from two to three are taken daily. One hour after its administration its odor is perceptible in the patient's breath. The curative effect is said to be rapid, especially in putrid bronchitis and pulmonary gangrene. Myrtol exerts no action over the tubercle bacillus. The intestines of patients who have died while taking this remedy retain the order of myrtol for some time.—*Wiener klin. Wochenschrift*, January 17, 1889.

Mechanical Treatment of Tabes Dorsalis.—A singular method of treating cases of locomotor ataxy has, during the past three months, been tried at the Salpétrière, and the results have been so satisfactory that M. CHARCOT recently devoted one of his lectures (*Progrès Médical*, Jan. 19th) to the subject, demonstrating the cases so dealt with. The practice is not absolutely novel, since in 1883 it was brought forward by Motchoukowsky of Odessa, who claimed that twelve tabetics had been greatly benefited by it, and also that the plan was of use in cases of sexual impotency apart from tabes. Last year M. Raymond, when on a visit to Russia, heard of the practice, and introduced it to M. Charcot's notice, and, as above said, it has been adopted in M. Charcot's wards during the past three months, the "chef de clinique," M. Gilles de la Tourette, superintending it. It simply consists in suspending the patient by means of Sayre's "jury-mast" for a period beginning with a duration of half a minute and progressively increasing up to three or at the most four minutes, an interval of two days occurring between each suspension. In order to exert greater traction on the spinal column, it is well to raise the arms every fifteen or twenty seconds. Eighteen tabetics have thus been treated, embracing about 400 "suspensions." Excluding four who were not suspended more than three times, the improvement was marked in fourteen, and eight of these most remarkably. They were all confirmed cases, and had mostly been treated by cauterization along the spine. Almost from the commencement of the suspension treatment the patients would improve in walking—an improvement at first temporary, but after eight or ten suspensions becoming continuous. They could then stand more easily, and walk without assistance. After twenty or thirty suspensions Romberg's symptom disappeared. There was also relief from vesical troubles, when these existed; diminution and even disappearance of lightning pains; return of sexual desire and capacity. Anæsthetic and other sensory disturbances also disappeared, and the general condition of the patient improved, sleep being better, etc. One case had a return of lightning pains whilst being treated, but subsequently again underwent improvement, which in all the rest was uninterrupted. In no case did the knee-jerk return, or the pupil reaction become normal. The method has also been applied to a few non-tabetic cases, as Friedreich's disease, neurasthenia, and disseminated sclerosis; but, as M. Charcot observes, the method is still in the experimental stage. So far, the results in tabes are encouraging, whilst the simplicity and harmlessness of the method are additional recommendations for its further trial.—*Lancet*, January 26, 1889.

Chloride of Iron in Diphtheria.—DR. KNITSCHOFSKY advocates the administration of chloride of iron in diphtheria. He prescribes for it as follows:

℞.—Tincture of chloride of iron . 8 parts.
Glycerine . . . . . 15 "
Water . . . . . 180 " —M.

For children, one teaspoonful every two hours; for adults, from a teaspoonful to a dessertspoonful every two hours or oftener. Dr. Knitschofsky has frequently tried this remedy, and has come to the conclusion that as much as one teaspoonful can be administered every half hour without danger.—*Wiener klin. Wochenschrift*, January 17, 1889.

Treatment of Typhoid Fever in Children.—DR. H. GILLET recommends the following: To reduce the temperature wrap the little patient in blankets saturated with the following:

℞.—Vinegar . . . . . ℥viij.
Carbolic acid . . . . . 15 grs.
Oil of thyme . . . . . 5 drops.—M.

Of the antipyretics quinine is the best (four grains for a child from one to two years of age); still salicylic acid in the same doses is often of service:

℞.—Salicylic acid . . . . 4 to 6 grs.
Brandy . . . . . ℥iss.
Syrup of orange-flowers . . ℥iss.
Lettuce water (Fr. Ph.) . . ℥ij ℥ij.—M.

If sore throat supervenes, it should be treated with gargles of glycerine and borax. Stomatitis, if present, requires local applications of chlorate of potassium.

To overcome constipation injections of glycerine, or the administration of manna or of castor-oil, are of service, or the following can be tried:

℞.—Scammonium } . . . āā ¼ grain.
Calomel }
White honey . . . . ℥iv.—M.

For a child one year old divide this into three portions and administer at intervals of ten minutes.

If there is diarrhœa, wash out and render the intestinal canal aseptic with the following:

℞.—Boracic acid . . . . 3 parts.
Boiled water . . . . 100 "

Never use phenic acid, as it is dangerous. To overcome the diarrhœa proper inject:

℞.—Infusion of camomille . . ℥iss.
Starch . . . . . ℥j.
Laudanum (Sydenham)
one year old child . . ½ drop.
two to three years old . . 2 drops.—M.

Should there be any cerebral excitement present, administer musk, camphor, bromide of sodium or chloral in orange-flower or cherry-laurel water. An infusion of roasted coffee is at times serviceable and well liked by children.—*Revue Gén. de Clinique et de Thérapeutique*, January 16, 1889.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

MASSAGE IN THE TREATMENT OF EYE DISEASES.

IN an address upon this subject, made at the recent Cologne meeting of the German Naturalists and Physicians, DR. PFALZ, of Düsseldorf, calls renewed attention to the matter, and chides the silence of others. While Pagenstecher's recommendation of this means of treating various affections of the anterior segment of the eyeball, and especially of clearing up corneal opacities, has doubtless been widely adopted; and the ointment of the yellow oxide of mercury, commonly used as an adjuvant, is often called by his name; it is yet a fact that not much has been written upon the subject. Many text-books make little or no mention of massage, and the matter probably lacks deserved attention.

For the clearing away of opacities in the cornea, numerous medicaments in the form of solutions, powders, or ointments, had long been employed, and among them the amorphous precipitates of mercury; but it seems to have been by Pagenstecher first that the *rubbing* was emphasized as an important element in the use of stimulating ointments; and others have proven its efficacy by omitting not only the medicament, but also the lubricant which he directed. Pagenstecher first commended its use for episcleritis and pannus; later for most slow and chronic affections of the anterior segment of the eye, except when iritis was present—involvement of the iris constituting a distinct counter-indication to its employment. This view is so far modified by Pfalz as to include chronic *plastic* iritis and its results among the conditions in which massage may be employed, after the more acute stage is past, with safety and sometimes with marked benefit. Serous iritis seems always very intolerant of such treatment, and little benefited by it, when borne. The value of the measure in lid-affections has been less noted; and while claiming for it but a limited range of application, Pfalz urges its usefulness in blepharitis, follicular conjunctivitis, and other chronic inflammations of the lids and conjunctiva, basing his views upon the anatomical disposition of the blood and lymph vessels, as well as upon clinical observation.

Theoretically, massage empties the vessels, and their refilling takes place not only from the capillaries, but also by imbibition from the tissues; while increased tone of their walls lessens the tendency to subsequent dilatation. Exudations are diffused over a wider area, and their absorption thus facilitated; while the circulation is quickened, and perhaps the trophic nerves stimulated, by the gentle irritation. Of course, only certain tissues are open to such direct action of the massage; yet it is claimed that the effect extends much further, and that notable reduction of the intra-ocular tension may be secured by this measure alone. Whether the vessels of the iris can be emptied by massage, as Pfalz claims, is probably like several of the points discussed, not beyond question; such, at least, is the explanation which he urges for the widening of the pupil which he observes as a result of the manœuvre.

Several cases are upon record where a sudden obscuring of vision has disappeared after rubbing the eyes; and the nature of the case and the subsequent history made it very probable that stasis in the retinal vessels, due to embolism or thrombosis, had been present and yielded to the massage. An unmistakable case of thrombosis of a retinal artery so relieved, has just been reported by Hirschberg.

Massage has also been utilized, after Förster's method, to triturate the lens-substance of slow-ripening cataracts, in order to hasten the maturation, and also to promote the absorption of a soft cataract after discission. Probably under the same title can be included the measure advocated by Michel—passive motion of a paralyzed or paretic muscle by grasping the tendon with fixation forceps and exercising the defective muscle by gentle stretching, alternated with stretching of its antagonist. Each of these procedures has met with more or less of success when conscientiously carried

out in suitable cases; and the negative or unfavorable results sometimes reported may often be ascribed to the operator rather than to the measures themselves.

The great drawback to the wider utilization in many cases, is the time that it takes. While a couple of minutes is all that is usually wise to expend upon any one region, this is too often more than the surgeon is willing to give. He therefore relegates the matter to some attendant, with the result that the method if properly applied at all, is not judiciously directed, as it must needs be in order to obtain the best results. These are potent and by no means harmless procedures, and their abuse may more than undo any good effects.

In its ordinary application to affections of the anterior segment of the globe, the lids should be gently closed and drawn a little tense by the fingers of the operator, and then *lightly* stroked by quick passes of the thumb, the index finger, or a cotton pledget. For the cornea, radiate stroking of one sector at a time is the best, carried, of course, from centre to periphery; circumcorneal lesions may be rubbed by a circular motion. In the case of the lids, the movement should be from internal to external canthus along the upper or the lower margin of the tarsus, and may be continued out and down upon the cheek along the course of the vessels. So employed at intervals of from one to three days, massage acts as a decided stimulant, reddening the eye for a short time, but generally soon reducing any congestion present. Any desired medicament may be rubbed in by the manipulation, the yellow oxide ointment being a favorite. (A salve so used must be free from all gritty particles, a condition most easily obtained in that of the yellow precipitate by adding an equal proportion of oleic-acid and rubbing it up with vaseline; the resulting orange-colored ointment in a few days becomes pale yellow and transparent from solution of the mercurial salt). Where the palpebral conjunctiva is the affected tissue, the everted surface of the lid may be rubbed.

As an explanation of some of the effects of massage upon corneal opacities, Pfalz points to the findings of the corneal microscope, which demonstrates in many cases tracts of vascularization, generally superficial, which are very prone to congestion upon slight cause. These he has rarely been able wholly to get rid of; but improved tone has lessened their irritability and their size has been reduced, so that they and the surrounding infiltration have ceased to be so great an obstacle to distinct vision. Old cicatrices may grow little if at all thinner; yet the smoothing of their superficial roughness may lead to a marked improvement in the visual sharpness. One case which Pfalz cites seems an extreme one, where in an interstitial keratitis with involvement of the iris, which had proved very rebellious, the vision was raised in four days from counting fingers at three feet to $\frac{4}{24}$, and in twelve sittings to $\frac{2}{3}$.

The applications of massage are thus claimed to be more extensive than generally thought; and the paper of Dr. Pfalz, while decidedly enthusiastic, seems to merit careful consideration. American ophthalmic surgeons have long made some use of massage, but certainly few can claim to have given it such a test as here described: and while the results have not generally been so brilliant, and have often been ascribed to the medicament employed rather than to the manipulation, it seems well to invite renewed attention to the subject, in the hope that more extended and careful tests will confirm the claims that are urged by its advocates.

STROPHANTHUS.

WITHIN the last few weeks, discussions of considerable interest to every one have taken place in the medical societies of the European continent, as to the relative value of strophanthus and kindred drugs. In the *Gazette Hebdomadaire* of January 18, 1889, and in *L'Union Médicale* of January 17, 1889, is a brief account of the transactions of the Académie de Médecine on January 15th, in which DUJARDIN-BEAUMETZ expressed the thought that, in his opinion, strophanthus is to be regarded as a tonic of great value in cardiac enfeeblement, possessing no deleterious renal effects, unless acute nephritis exists, when, by reason of its stimulation of the renal epithelium, it may do harm. In renal incompetence it is superior to digitalis. One of its disadvantages, he asserts, is the production of diarrhœa by its prolonged use. The assertion of Cazeaux, that it might produce nephritis, he regarded as exceedingly doubtful, except in exceedingly rare cases, and he found that it acted very happily as a diuretic when such action was desired, and with marked rapidity in the dose of five or six drops of the tincture morning and night. Altogether, Dujardin-Beaumetz regards strophanthus as a singularly valuable addition to materia medica.

At a later meeting of the Académie de Médecine, Germain-Sée read a paper on the same subject. He asserted that the action of the alkaloid was incontestably superior to that of the crude drug, in exactly the same manner as morphine and atropine are better than opium and belladonna. In mitral and aortic insufficiency it seemed to be particularly useful.

Apropos of these remarks, Sée attempts to establish a series of cardiac remedies in classes according to the state against which they are directed. These are those which are respiratory in action, or especially directed against dyspnœic symptoms, and consist of iodide of potash, atropine, pyridine, and erythrophleine, and those which are tonics to the heart, as sparteine, strophanthine, digitalis, convallaria; thirdly, those of diuretic power, namely, caffeine, and similar drugs.

Both Dujardin-Beaumetz and Constantin Paul discussed the paper at the meeting, the latter recommending an extract of strophanthus.

Again, in *Nouveaux Remèdes* of January 24, 1889, Bucquoy contributes an article on strophanthus, in which the value of the drug in aortic disease is particularly noted; the benefit in cases of angina pectoris and the non-cumulative tendencies of the drug are all insisted upon. Still more recently, in the *University Medical Magazine* for March, Hare has recorded its value in the cardiac diseases of young children where digitalis fails.

The annual report of Dr. Wm. K. Newton, Dairy Commissioner of the State of New Jersey, recently presented to the legislature, shows very favorable results from the enforcement of the law regulating traffic in milk and oleomargarine. That part of the report relating to the adulteration of foods and drugs furnishes information which will not be relished by the citizens of New Jersey. Of the 623 articles of food subjected to analysis, more than 48 per cent. were found to be adulterated; and of the 415 samples of drugs and medicines analyzed, more than 55 per cent. were adulterated, or below the legal standards.

Adulterations were detected in lard, coffee, canned goods, honey, ground spices, cream of tartar, olive oil, and numerous drugs and medicines. Some of the adulterants were of such a nature as to be injurious to health, others, and the most of them, were harmless. The selling of a debased article, though harmless, is an imposition, which in the case of medicines may place life in jeopardy. The Commissioner deserves great credit for the active warfare waged by him and his associates against these nefarious practices.

It is stated that Dr. Gamaleia, of Odessa, who claims to have discovered a method of vaccination against cholera, will go to India next month to pursue his investigations.

A hospital located within the walls at Jerusalem has unsanitary conditions of so grave a nature as almost to challenge its usefulness. It is described as having no drainage, and in a crowded situation where the streets are narrow, and into which refuse of every description is thrown, the effluvia from which is indescribable. In the courtyard of the hospital is an opening or vent from an extensive old cesspool partially underlying the building, and from it a stream of foul air is constantly pouring through the wards, which are damp, unventilated, and without the means for heating. It would be a charity to abandon such a charitable institution as this, if this is a true description.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Section on Neurology.

Stated Meeting, February 8, 1889.

Landon Carter Gray, M.D., Chairman.

Dr. J. Arthur Booth reported

A CASE OF TUMOR OF THE CEREBELLUM.

The patient was a girl, ten years of age, who was seen in consultation February 19, 1888. The family history was good, and the child had previously had no serious illness. When three years old she fell down a flight of steps, striking her head upon the stone walk. In November, 1887, it was noticed that she was losing flesh, and she began to have attacks of headache and vomiting. She became very irritable, and indisposed to exertion, and it was noticed that she carried her head as though her neck was somewhat stiff. From the middle of January she complained of pain in the back part of the head and the neck, principally on first awakening in the morning.

On examination, February 19th, she was found to be dull, listless, and very weak. Complained of severe head pain. Speech normal; no deviation of tongue. Vision was apparently normal, and there were no changes in the fundus; but the pupils were dilated, and there was no reaction to light. There was slight paresis of the right external rectus, but no paresis of face or limbs. Knee-jerks absent; no anæsthesia. There was marked sensitiveness to touch all over the head, and especially on the

back of the neck just below the occiput. Posterior cervical glands quite large. The temperature was 101⅜° and the pulse irregular, and the diagnosis made was tubercular meningitis. Tumor of the cerebellum was considered, but the absence of optic nerve changes, and the presence of an elevated temperature, with irregular pulse, seemed to indicate the condition named.

Increasing doses of iodide of potassium were ordered, and on February 24th the patient's general condition was found to be worse, though the temperature was now 100°, and the pupils were less dilated and reacted to light. The ophthalmoscope, however, showed commencing optic neuritis.

On March 5th the first well-marked convulsion occurred, and this was followed by many others, five or six during the day. These consisted of tonic spasm of the limbs, and drawing up of the right side of the lip and nose; the right eye being tightly closed, and the left eye wide open. On two occasions only was consciousness said to be entirely lost. The symptoms were now regarded as pointing to an intra-cranial, and probably cerebellar, growth. On March 9th she was much prostrated, and it was found impossible to retain the iodide, the doses of which had been previously much diminished on account of vomiting. Stimulants were consequently given, with syrup of the iodide of iron, and inunctions of cod-liver oil. Later, there was some improvement, and the vomiting ceased. She passed her urine involuntarily, however, and the act was generally accompanied by one of the convulsive seizures described. The urine contained a trace of albumin, but was otherwise normal.

On March 25th, the ophthalmoscope showed advanced atrophy of both optic nerves, and by July 1st the patient was entirely blind. At the latter date she lay most of the time in a semi-comatose state, and had occasional attacks of *petit mal*. There was now paralysis of right side of the face, partial paraplegia, and paresis of the left arm. The following bulbar symptoms had also appeared: dulness, impaired articulation, difficult deglutition, and polyuria. There had been for some time a gradual enlargement of the head, and by August 1st there was some separation of the coronal and sagittal sutures. She failed steadily, and died August 17th.

At the autopsy, nine hours after death, the whole head was found very much enlarged; the frontal and parietal bones being very thin and separated at the sutures to a marked degree. The dura mater was very thick and distended, and, on puncturing it, a large quantity of clear fluid gushed out. The convolutions were flattened, and the whole brain was pale, flabby, and softened. The lateral ventricles were much dilated, containing a large amount of fluid, and the medulla was flattened, compressed, and softened. The optic nerves were small. Directly between the lateral lobes of the cerebellum there was found a large nodular growth, three inches long, one and a quarter inches wide, and one and a quarter inches in its vertical diameter. It was attached to the right lobe, occupying quite an extensive hollowed-out space in the lobe, and also extended into the fourth ventricle, pushed the medulla to the left, and pressed upon the right crux of the cerebellum. The microscopical examination of the tumor by Dr. Frank Ferguson, showed a large number of spindle cells, medium in size, imbedded in an abundant granular and fibrillated stroma, with a rich vascular supply. The walls, being composed of embryonic tissue, were quite thick, and gave the growth the appearance of angio-sarcoma. The tumor was cystic in places.

DR. GRAEME M. HAMMOND then read a paper on

THE PATHOLOGY OF TONIC AND CLONIC SPASMS.

The present paper, he said, was to be regarded as a preliminary one, to be followed by a second paper embracing the subject of spasm in all its details. On this occasion he proposed to consider spasm of cerebral origin, and due only to undoubted organic lesions. The only two forms of spasm which we can recognize at the present day are: 1, that in which the muscles affected are stiff, rigid, and contracted, to which the name of tonic or spastic spasm has been given; and, 2, that known as clonic or mobile spasm, in which the muscles are either the seat of regular and rhythmic contractions (tremor) or are affected with incoördinate, irregular movements, variously designated as chorea, athetosis, and ataxia.

In regard to the seat of the pathological lesion of spastic spasm all authorities are agreed that the condition is produced by an irritation situated in the white conducting nerve fibres of the motor tract; but in regard to the situations of the pathological lesions of mobile spasms the authorities are by no means so positive. Sharkey concurred in the opinion of Demarge, that mobile spasm in any form may be due to a lesion situated in any part of the motor tract, and other authors, such as Kohler and Pick, Ricci and Bidon, either coincided with this view or confessed that the subject was completely shrouded in obscurity; while Stephan located the lesion in the thalamus, and Charcot and Nothnagel in the thalamus and the posterior third of the internal capsule. It was in the hope of throwing a little more light upon the subject, Dr. Hammond said, that the present paper was written.

After some preliminary remarks on the selection of cases he took up each variety of mobile spasm separately; commencing with paralysis agitans. In this affection, as in all the other varieties of this form of spasm, except that due to disseminated sclerosis, he carefully excluded all those cases in which the lesions were so extensive as to make the cause of the spasm a matter of doubt. In 1883 Demarge reported a case in which the patient was suddenly seized with right hemiplegia, hemianæsthesia, and hemiparalysis agitans, where the autopsy showed two small foci of softening in the posterior portion of the lenticular nucleus, which, though bordering on the posterior third of the internal capsule, did not involve it in the slightest degree. In a case reported by Hamilton, in which the affection was limited to the right arm, a tumor was found limited to the substance of the left optic thalamus. In two cases reported by Parkinson and Oppolzer, respectively, there was found induration of the pons, medulla, and cervical cord. In a case reported by Dorvie there were miliary changes in the corpus striatum and hemispheres. In a case of Anton Herman's the only lesion found was a chronic meningitis. In a case reported by Galvagni in which hemiplegia of the right side was followed by ataxia when voluntary motion was attempted, and by tremor not unlike that of paralysis agitans, the only lesion discoverable was a spot of softening in the middle of the left optic thalamus. Of other cases of paralysis agitans reported, in some no lesion whatever could be found,

and in others multiple lesions were observed occupying the central ganglia, internal capsule, pons, cerebellum, and spinal cord.

In disseminated cerebral sclerosis it was very difficult to find cases, from the very multiple nature of the disease, where the symptoms of tremor on voluntary motion only could be attributed to an isolated lesion; yet a few cases of this description were on record. Having referred to cases of Demarge, Gray, and Sharkey, he mentioned one of his own, not yet reported, in which the patient began to notice that the left hand was gradually becoming weak and anæsthetic. Shortly afterward tremor was observed whenever he attempted to use the arm, and these symptoms slowly increased until, in about a year's time, the arm became useless from paresis, anæsthesia, and tremor. The patient died from pneumonia, and the autopsy revealed a spot of softness in the posterior internal part of the optic thalamus. Many cases, he said, were on record of lesions scattered throughout the white matter of the brain without involving the cortex or basal ganglia; but in all these there was either no tremor present or else the lesions involved the cell area of the pons.

In regard to the pathological anatomy of athetosis he said he had seen no reason to change the views expressed in his paper on that subject read two years ago before the New York Neurological Society, in which he reported nine cases of athetosis accompanied by autopsies. In three of these the lesions were confined to the corpus striatum, and in two to the optic thalamus. In three cases both these ganglia were involved, and in two the lesion was in the cortex, in the motor region. To these cases three more, collected by Stephan, could be added. In the first two there was softening in the optic thalamus, and in the third the lesion involved both the optic thalamus and the posterior part of the internal capsule.

Similar lesions had been observed in chorea of cerebral origin, either pre- or post-hemiplegic. Mitchell reported two cases in which the lesion was found in the corpus striatum on the opposite side, and Charcot three cases, in the first of which the lesion was situated in the posterior extremity of the optic thalamus, while in the second and third the posterior part of the caudate nucleus and the posterior part of the internal capsule were involved. Similar cases had been reported by Demarge, Reymond, Nacier, Sturgis, Stephan, and others.

The pathological anatomy of cerebral ataxia is in no wise different from that observed in athetosis and chorea. Gower reported a case in which the lesion was found in the left optic thalamus, and Demarge five cases in which the lesions were in the left lenticular nucleus, optic thalamus, and internal capsule, and in the right optic thalamus. Other cases reported by Reymond, Charcot, and others, only added to the number of cases, without indicating any other situations of lesions.

Taking these cases together, it can readily be seen that in all of them, without exception, the lesions were found constantly in three areas, viz., the cortex, the optic thalamus, and the corpus striatum. In a careful examination of all cases, it would be found that when the anterior two-thirds of the internal capsule are involved, spastic spasm is invariably present. In a case of Sharkey's, classified under the heading of disseminated sclerosis, which, beginning with tremor on one side, soon passed into a condition of spastic spasm, while a gradual onset of tremor occurred in the other side, both optic thalami were found involved, but only one internal capsule. Sharkey regarded all the symptoms as attributable to invasion of the internal capsule; but Dr. Hammond was of the opinion that only the spastic spasm, which was confined to one side, was produced by the lesion in the internal capsule, while the bilateral tremors were due to the implication of the optic thalami. While several cases had been reported of disseminated sclerosis, in which no tremor was observed, this was because the disseminated patches did not involve the basal ganglia or the cell area of the pons.

In conclusion, he said that from a study of these cases he could not agree with Demarge and Sharkey, that mobile spasm may be due to any part of the motor tract; nor with Stephan, that the lesion is in the optic thalamus; nor with Charcot, that it is in the thalamus, and, in addition, the posterior third of the internal capsule; but he believed that it may be produced by any lesion of an irritative nature situated in any part of the brain where nerve cells are located—these cells being located in the cortex, optic thalamus, corpus striatum, and pons; the difference in the form of the spasm, he thought, was one of degree, and not one depending on the location of the lesion; and it was, therefore, impossible from the symptoms to differentiate between a lesion of the cortex, optic thalamus, and corpus striatum.

DR. LANDON CARTER GRAY presented

A REMARKABLE CASE OF PROGRESSIVE MUSCULAR ATROPHY

in a male patient, thirty years of age. It is an instance of the so-called "juvenile type" of progressive muscular atrophy, as described by Erb, of Heidelberg, in 1884. It is, he said, the purest case—indeed, the only pure case—that he has ever seen; the limitation of the atrophy and hypertrophy being exactly as described by Erb. He believes that this is the first case that has been met with in this country, although a case of Dr. Putzell's, published in the *Reference Hand-book of the Medical Sciences*, was very closely akin to this type. It differed from it, however, in the distribution of the atrophy, in the presence of marked sensory symptoms, and in the onset of the disease with slight cerebral symptoms.

Dr. Gray stated that he has but little faith in this type-making business, because of the failures of the predecessors of Erb in this line, such as Hemptenmacher, Eichhorst, Zimmerlin, Leyden, and Moebius. He then went on to speak at some length of his reasons for believing that this type often merged into others.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, February 5, 1889.

THE PRESIDENT, GEORGE W. JACOBY, M.D., IN THE CHAIR.

DR. CHRISTIAN A. HERTER read a paper entitled

A STUDY OF EXPERIMENTAL MYELITIS.

The object of the paper was twofold; first, to show that it is possible to give rise to an acute localized myelitis in animals (cats, rabbits, dogs) by temporarily shutting off the blood supply of the spinal cord; secondly, to describe in detail the histological characters of the pro-

cess thus induced. Stenson's operation, as modified by DuBois-Reymond, was used to deprive the cord of its blood-supply. This consists in passing a curved needle through the abdominal wall on one side of the vertebral column, and bringing it out on the other, in such a manner as to include, among other structures, the aorta and vena cava. The needle carries a strong ligature, which is tied so tightly over the back of the animal as to compress effectually the abdominal vessels. The spine of the fourth lumbar vertebra is the level at which the needle is passed. The effect is to produce an almost instantaneous paraplegia. If compression be exercised for a shorter time than three-quarters of an hour, the paralysis wears off rapidly; if for more than an hour, it becomes permanent and does not diminish during the life of the animal.

In these cases lesions of the cord, peripheral nerves, and muscles could regularly be detected shortly after the operation. Pathological changes were visible in the anterior horns of the fifth and sixth segments as early as twenty-four hours after the operation. In a few ganglia cells the cell-body was pale and swollen, and the nuclei were obscured. Twelve hours later, a larger number of cells was involved, and many had lost their processes, and, in some instances, their nuclei. After a lapse of seventy-five hours, the necrotic changes in the ganglion cells were much more intense, and involved, at least to some extent, about one-half of the cells in each section. In consequence of these changes in the ganglion cells, the anterior nerve roots had undergone partial degeneration. Sections stained by Weigert's method showed that the fine network of medullated fibres of the gray substance was also distinctly altered in places. Many of the vessels and perivascular spaces showed evidence of inflammatory change. By the end of the sixth day, the inflammatory process was much more advanced. Twelve days after the operation, no normal ganglion cells could be found in the fifth and sixth lumbar segments. After thirty days, the nervous elements of the central gray were all but completely destroyed. In a majority of sections from the most diseased region, no ganglion cells could be detected. Nothing remained of the network of medullated fibres. The anterior horns were completely degenerated. The posterior nerve-roots were infiltrated with small round-cells, as was also the intervertebral ganglion. The spinal nerves derived from the diseased portions of the cord underwent degeneration closely resembling that occurring in distal parts of divided nerves. Interesting changes were found in the muscles. Hemorrhages into the perimysium were visible in the first week. By the sixth day, a curious condition of vacuolization was found in individual fibres which, by the thirtieth day, could only be detected here and there. At this time, the majority of the fibres had undergone simple atrophy, and coincident with this change there was hyperplasia of the interstitial connective tissue. Many of the larger fibres had undergone granular degeneration. In long-standing cases, the bladder was the seat of great muscular hypertrophy and connective tissue hyperplasia. In non-pregnant females, the mucous membrane of the uterus was regularly the seat of hemorrhagic infarctions. In Stenson's experiment, we have a method of inducing a form of myelitis in animals which, in certain stages, bears a close resemblance to processes which occur in man. This fact suggests that interference with the blood-supply of the human spinal cord may be an etiological factor in some varieties of myelitis. A few cases have been recorded which justify the suspicion that embolism of the spinal cord can give rise to an acute myelitis, and it is not improbable that other causes of vascular obstruction may produce the same effect.

DR. HEITZMANN felt that he could discuss the subject of myelitis intelligently, after having studied it twenty-five years. Experimental myelitis had been the object of much careful work in his own laboratory by Emerson, Rockwell, and Boyer. The results of their work had been published in this country, and he wondered why Dr. Herter had ignored them. He could understand the writer's taking the ground of his teacher that there is an emigration of leucocytes, and not a proliferation of neuroglia cells. Why was Cohnheim ignored? In the drawings accompanying the paper he had noticed œdema very distinctly, but Dr. Herter had not mentioned its presence. This œdema was, no doubt, the cause of the change in shape of the central canal. In his opinion, the gray matter itself furnishes most of the corpuscles which Dr. Herter called leucocytes. This he had learned from his own laboratory work, and Robinson had shown twenty-five years ago, by producing inflammation in the sympathetic ganglia, that the ganglion cells plainly break up into these corpuscles. They are not replaced by leucocytes, but through nutritional changes fall back into embryonal conditions. What right have we to speak of connective tissue in the gray substance? It is protoplasm full of activity. To show these changes osmic acid, bichromate of potash, and chromic acid should be used, and not alcohol, which he supposed the author had employed. There is not a single proof that leucocytes, even if present, ever form connective tissue. As to the myositis, he supposed the author would refer that too to emigration of leucocytes into the perimysium.

DR. SACHS thought that the point of greatest importance established by the author was that the cells of the anterior horns are the first to be changed. The theory of Strümpell and others as to the infectious nature of some spinal cord diseases, might often be explained, perhaps, by vascular changes. Possibly bacterial occlusion of spinal vessels might cause acute poliomyelitis. The muscular changes described by the writer were different in man. In animals vacuolization was early, but in man after long-continued chronic disease of the muscles.

DR. MARY PUTNAM JACOBI was particularly struck by the apparent identity of symptoms produced by cutting off the blood supply, and by furnishing blood in excess. Some of the older experimenters had occluded arteries by the injection of powders. The author's contribution confirmed Ranvier, that the first step in inflammation was change in nutrition. The question had occurred to her, whether all these vascular alterations were not the immediate result of loss of directive power over the bloodvessels by the cells which govern.

DR. JACOBY had examined Dr. Herter's specimens microscopically, and there was no doubt as to the changes in the posterior roots. He did not think the alterations in the muscles were properly vacuolization, not such as in Wagner's specimens, which he had also seen. It was a question if all the changes were due to the cord lesion.

DR. HERTER closed the discussion. As to Dr. Heitzmann's criticisms, to answer him would involve a reconsideration of the whole question of inflammation, as his

views upon that subject seemed to be so sweeping and revolutionary that they would require more examination and thought than he was able at the time to give them. His specimens were many of them examined in the fresh state, and some after hardening in Müller's fluid. They were not treated with alcohol. As to there being no connective tissue in the spinal cord, this was at variance to the generally accepted ideas, and it was difficult for him to conceive of its absence. He knew of the experiments referred to by Dr. Mary Putnam Jacobi, but thought they were confined more to the study of grosser effects and lesions, and not to the study of microscopical changes.

DR. SACHS then presented a case of

HEMIPLEGIA WITH REMARKABLY PERFECT ASSOCIATED MOVEMENTS

on the paralyzed side. It was a young man of twenty-three, who had infantile hemiplegia at the age of one year, as the probable result of a fall. The paresis, contractures, and exaggerated reflexes of the left side, were the remnants of this early attack. He also described a second case, who failed to put in an appearance at the meeting, a girl of twelve, whose early history was very obscure, but whose physical symptoms pointed to a similar attack in early life. Both cases presented the marked peculiarity that all the movements of the sound arm and hand were imitated by the paretic members, and *vice versa*. The same was true to a less degree of the lower extremities. In Case I. if he attempted to raise his left arm the right would also be raised; in lifting a glass from the table with his left hand, the right would perform the same movements. They were very marked in buttoning or unbuttoning his clothes, when the paretic hand would make the same motions, In Case II. these delicate movements were also present, but the grosser kinds were not imitated by the paretic hand.

Some charts, designed by Dr. Peterson, were exhibited to show the resemblance between the original and the associated movements. They were copies of zigzag lines made by the patient on a horizontal blackboard with a piece of chalk in each hand. Dr. Sachs remarked that it was difficult to explain these associated movements, and that it was curious that the very members of our bodies, which are innervated from our earliest days, should perform associated movements in disease. It was supposed by some that inhibition having been removed by cortical or intra-cerebral disease, the natural tendency to bilateral movements returned, and that the paretic hand was moved from the sound half of the brain. There were numerous objections to this theory, and it could not explain the associated movements of the sound hand when attempts were made to move the paretic hand. The speaker thought it more probable that an irradiation takes place lower down in the central nervous system, either in the pons, medulla, or even in the spinal cord, and that these associated movements are to be regarded as imperfected reflected movements. He did not think that such movements could be explained by the supposed existence in many persons of an unusually large number of uncrossed motor nerve fibres.

DR. HERTER asked if there were athetosis and atrophy in the cases, and was answered that there was as much atrophy as usual in cerebral cases, but no athetosis.

DR. LESZYNKSY had noticed in such cases that when the attention of patients was directed to the paretic hand these associated movements occurred, but not otherwise.

CORRESPONDENCE.

ON THE CLINICAL APPLICATIONS OF BARIUM.

To the Editor of THE MEDICAL NEWS,

SIR: In your last issue, Dr. Hobart A. Hare appears with an interesting paper on the clinical applications of barium. He quotes the opinions and observations of foreign physicians only, thereby implying that on this side of the Atlantic the remedy is ignored or is unknown. If he will kindly refer to pages 229–231 of a *Treatise on Materia Medica and Therapeutics*, by Roberts Bartholow, M.D., sixth edition, he will find a tolerably full account of the actions and uses of barium. Dr. Hare cannot be expected to look over old editions of this book, and, therefore, I take the liberty to acquaint him with the fact that an article on barium was inserted in the fourth edition of this work, published in 1881. The following sentence gives a summary of the views held by the author of the work above referred to, on the subject of the uses of barium:

"Barium chloride has proved useful in hemorrhage, acute congestion of organs, atony of the bladder, atony of the intestines with deficient secretions, and in weakness of the heart with low arterial tension, and for effecting the removal of inflammatory exudations," etc.

To this statement I can add some recent personal experience: Barium chloride has proved to be remarkably successful in *the treatment of varicose veins*. Within the past few years various cases of *aneurism* have been reported in current medical literature cured by it.

As during the whole time of my residence here I have included an account of barium in my regular annual course of lectures, both didactic and clinical, the students of Jefferson Medical College can testify as to the accuracy of the above, if further testimony be necessary.

ROBERTS BARTHOLOW, M.D.

PHILADELPHIA, Feb. 18, 1889.

OPERATIVE PROCEDURES IN HYPERTROPHY OF THE PROSTATE.

To the Editor of THE MEDICAL NEWS,

SIR: *Apropos* of an article in THE MEDICAL NEWS of Jan. 19th, under the title "Operative Procedures in Hypertrophy of the Prostate," I make the following report:

J. G., a large fleshy man, aged seventy-nine, an engineer by profession, applied to me December 15th for relief from retention of urine. He had been subject to attacks of dysuria for many years, and in the summer of 1887 had fallen astride of the gunwale of a boat and bruised his perineum to such an extent as to produce a traumatic stricture, which closed the urethra to the introduction of the smallest instrument. The urine, however, had continued to dribble through with increasing difficulty, until the date of his application to me, when the retention had become almost complete.

On examination the prostate was found to be as large as a good size orange, filling the rectum to the obstruction of gas, as well as feces, the distended bladder, of course, assisting. The perineum was very deep, and

showed the results of the injury it had received, by an induration which extended from the bulb to the apex of the prostate. He could retain nothing on his stomach, and seemed to be suffering as much from obstruction of the bowels as from the retention of urine. What little urine he passed was slightly alkaline, but otherwise normal in every respect; in fact, there was no evidence that the kidneys had been affected by the obstruction to the flow of urine, which, from his account, must have existed to a greater or less extent for at least fifteen years.

The question was, What to do with him? Perineal section without a guide in the disorganized condition of the parts would prove to be a formidable undertaking. To "tap the bladder through the perineum and the enlarged prostate quite independent of the course of the urethra," considering the size of the prostate, I was not inclined. Aspiration would afford only temporary relief.

It seemed to be one of the few cases in which it is justifiable to open the bladder above the pubis. Accordingly in the presence and with the concurrence of Doctors George A. Sterling and W. H. Perdomo, a free opening was made with a bistoury through a thick layer of fat, almost down to the bladder, into which an ordinary trocar was then thrust, and the water drawn slowly off. A soft catheter was then introduced through the canula and retained. In addition to the relief of the bladder symptoms the patient was immediately able to pass a quantity of flatus which had distressed him greatly. Two days after, in a moment of irritation, he removed the catheter, which I was not able to introduce, the bladder being collapsed. The urine, however, passed freely through the opening without extravasation, a fact due to the size of the external wound, as I think, and continued to do so for a week, All this time he would have been very comfortable, but for the obstruction of the bowels. He could pass flatus but no feces, and retained nothing that he took into his stomach.

At this time the opening closed and the symptoms of retention reappeared, but were not so marked as before the operation. Three days later it reopened and the urine continued to flow through it until the patient's death, which took place on January 5th, eighteen days from the date of the operation.

On January 4th, the urine ceased to be secreted and he fell into a quiet stupor, breathing easily, without stertor. Soon afterward his breath took on a decidedly urinous odor, and there appeared on his nose, cheeks and side-whiskers, a copious white deposit, which I took to be urate of soda, though I had no means at hand to determine the fact. There was some about the mouth, or the under part of the nose, possibly because of the warmth and moisture of the breath. It continued for several hours and then ceased to form. On being wiped off, it did not reappear.

At the autopsy, the bladder with the exception of a slight thickening of the walls, was found to be in a sufficiently healthy condition, but the third lobe of the prostate projected into it at least an inch and a half. This was sessile, but soft and pendulous, and had a tendency to fall over toward the neck of the bladder in such a way as to block it up completely. The enlargement in this as well as in the other portions of the enormously developed glands, was simply hyperplasia with no heterogeneous elements in it.

There were no signs of extravasation of urine, or peritonitis. The suprapubic opening had evidently taken on the characteristics of a fistula with a living membrane of its own. The kidneys were not examined; partly from deference to the almost universal objection on the part of country people to the mutilation of the dead for scientific purposes, and partly from the fact that no symptoms referable to these organs had shown themselves until the last moment.

Now this man evidently did not die from the effects of operation. There was no shock. No rise of temperature. No extravasation or peritonitis. No signs of septic influence, unless the uræmia of the last twenty-four hours be classed under that head, and I do not think that the operation was to blame for that. He died of starvation, and the suprapubic opening in relieving him of the retention did all that any elaborate operation could have done, (I shudder at the thought that somebody might suggest colotomy). At the time of his death his bowels had not acted for nearly a month, and for three weeks he had taken nothing more nourishing than a little champagne and seltzer water. An injection thrown past the prostate was held by it as by a valve, and gave him so much distress that it was not repeated During this time he must have lost at least seventy pounds. He lived upon himself, a diet so largely nitrogenous as possibly to account for the accumulation of urates which took place toward the last.

The white deposit mentioned, I have never seen before, nor do I remember to have seen such a case reported.

J. H. ROGERS, M.D.

SAG HARBOR, LONG ISLAND, Feb. 11, 1889.

NEWS ITEMS.

Pharmaceutical Explosions.—According to the *Farmatzevtitchesky Jiirnal*, December 4, 1888, a sad accident recently occurred in the shop of a St. Petersburg chemist. A powdered mixture, consisting of an ounce of chlorate of potassium and one drachm of tannic acid, was ordered by a physician who probably had forgotten his chemistry. The chemist, who also ought to have known better, set to work to dispense the prescription, and was punished for his ignorance by a violent explosion of the incompatible substances. His hands were severely burned, and his beard and eyebrows were singed off. He was only able to resume his occupation several weeks afterward. A similar accident occurred about two months before at Warsaw, where a chemist tried to prepare a mixture consisting of chlorate of potassium, tannic acid, and oil of peppermint.—*Brit. Med. Journ.*, Feb. 2, 1889.

Corrigendum.

DECUSSATION OF FIBRES OF VOLUNTARY MOVEMENT.

In our issue of February 9th, page 160, the first and second conclusions on this subject reached by Dr. Brown-Séquard were stated as the reverse of what they should have been.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ACUTE PANCREATITIS.

A Consideration of Pancreatic Hemorrhage, Hemorrhagic, Suppurative, and Gangrenous Pancreatitis, and of Disseminated Fat-necrosis.

The Middleton-Goldsmith Lecture for 1889, delivered before the New York Pathological Society, Feb. 16, 1889.

BY REGINALD H. FITZ, M.D.,

SHATTUCK PROFESSOR OF PATHOLOGICAL ANATOMY IN HARVARD UNIVERSITY AND PHYSICIAN TO THE MASSACHUSETTS GENERAL HOSPITAL.

(Continued from page 203.)

HEMORRHAGIC PANCREATITIS.

IN considering the relation of hemorrhage to acute pancreatitis, it is important to agree upon what shall be understood by the latter term.

It has already been shown that the views advanced by Clässen and his predecessors give no aid in this matter. Klebs is non-committal on account of the paucity of evidence, and Friedreich elaborated his systematic description of acute primary pancreatitis from the consideration of four cases. In the one pancreas were multiple abscesses; in another a bloody exudation, and infiltrated blood in the vicinity; in a third were spots of finely granular, yellow exudation, with interlobular hemorrhage; while the fourth pancreas was gangrenous.

The material which had been accumulating since the publication of Friedreich's article, in 1875, is already so considerable and varied as to make possible a more complete description of the subject.

The acute inflammation of a gland, from the anatomical point of view, demands the presence of degenerative changes in the parenchymatous cells, or an exudation in the interstitial tissue, or both these factors.

The first, the parenchymatous inflammation, or granular degeneration of the pancreas, such as occurs in infective diseases, or as the result of mineral poisoning, is of no immediate concern. It is the interstitial variety which, with or without associated parenchymatous changes, may be regarded as the genuine acute pancreatitis; and it is in the interstitial tissue of the pancreas that the inflammatory exudation is to be sought. But this tissue is both fibrous and fatty, one or the other variety predominating in different individuals, and, perhaps, at different periods in life. These tissues bear a continuous relation to the peritoneum and to the subperitoneal and retropancreatic fat-tissue. It is, therefore, most probable that an inflammatory process of this fat-tissue might arise within the pancreas, or be continued to the pancreas from some more remote place of origin. Thus a primary and a secondary acute, interstitial pancreatitis might occur. The results in either case would be the same; the sources and progress of the disease might vary.

Whenever the anatomical evidence is insufficient to establish the diagnosis of inflammation, it is permissible to utilize the symptoms for this purpose. If the general symptoms of inflammation are present, and the pancreas is described as infiltrated with blood, such an association of symptoms and lesion is rather classified among the inflammations than among the hemorrhages.

Thus, Cases VIII. and XX. have many features in common; the latter, however, is tabulated as hemorrhagic pancreatitis, since it was considered clinically as a case of peritonitis from perforation. The former was placed among the hemorrhages, since the clinical picture was not that of an inflammatory process.

The series of cases which form the basis of this part of the subject naturally fall into three groups.

In the first hemorrhage is conspicuous, in the second suppuration, and in the third gangrene.

These may be designated respectively as hemorrhagic, suppurative, and gangrenous pancreatitis.

Before calling attention to the first of these groups it is desirable to exclude certain cases which have been regarded as possible illustrations of a hemorrhagic pancreatitis. Fearnside[1] reported the case of a man æt. forty-nine, not remarkably temperate, but who had enjoyed good health till within a year, since which time deep-seated pains in the region of the stomach had existed, with occasional heat or coldness in the same region, gastrorrhœa, pyrosis, constipation, pallor, and loss of flesh. For three months before death the pains became more severe and frequent, eventually constant, generally most distressing a few hours after taking food. Three days before death a sudden, excruciating pain occurred, followed by jaundice and a dark-brown vomit. On the following day there were intermitting vomiting and frequent hiccough. On the day of his death he was collapsed, although his intelligence was good. The epigastric pain was severe, and, on pressure between the navel and the ensiform cartilage, a deep-seated, transverse tumor could be felt. The pancreas was four times the normal size, and was adherent to the stomach by some firm adhesions. The neighboring peritoneum showed spots of soft and firm exudation. The greatest increase in size was in the head, which extended deeply into the right lumbar region. It was blackish-brown, pultaceous, grumous, and contained distinct blood-clots. In the more consistent portions there was no trace of natural gland-tissue. The body was firm and close in texture, of a dark red color, mottled with black lines and points, and became paler toward the lip.

The probability of this being a case of malignant disease with hemorrhage is very strong, especially as the appearances do not correspond with those to be stated later as found in hemorrhagic pancreatitis.

Rigal[2] reports the case of a man, æt. fifty-two, previously in perfect health, who suffered for seven days from

[1] London Medical Gazette, 1850, xlvi. 967.

[2] Gaz. des Hôp., 1869, xlii. 562.

intermittent fever, daily, with short remissions. The abdomen and legs then became swollen, and some pain was complained of at the right of the navel, where was a sensitive, indurated spot. Jaundice then occurred, also progressive weakness and epistaxis. Finally, fever was noticed, and death took place about seven weeks from the beginning of his sickness. The pancreas was large, the head being twice the normal size. The latter was brown, both on inspection and section. On microscopic examination there was advanced fatty degeneration, and numerous crystals of margarine were seen. There was also fatty degeneration of the right kidney and an enlarged and friable spleen. The liver was normal in size and consistency; the bile-ducts and gall-bladder were dilated.

This case is excluded from the list which is to follow, from the inability to determine the nature of the changes in the head of the pancreas. At the same time it is admitted that certain characteristics are presented which render it not unlikely to have been an instance of the disease under consideration.

The case reported by Huber[1] must be excluded from those of hemorrhagic pancreatitis. His patient died within twenty-four hours after the onset of an attack of severe, epigastric pain. There was a tumor of the head of the pancreas surrounding the common duct, which was passable. The tumor descended into the mesentery. It looked like Förster's carcinoma simplex, but had many pigmented and hemorrhagic spots.

The case of pancreatic hemorrhage reported by Challaud and Rabow[2] is also not wholly clear with reference to its relation to pancreatitis.

The patient, sixty-two years of age, an insane woman and inmate of an asylum, had an ovarian cystoma for several years.

She was found at bedtime, pale, and groaning feebly, without known cause. The next day she was collapsed. She complained of suffering, especially in the lumbar and epigastric regions. The pain was not increased on pressure, and there was repeated vomiting. She remained in a condition of extreme weakness, with frequent vomiting and groaning, a quick pulse, and a subnormal temperature till her death on the fourteenth day. The pancreas appeared doubled in size. On tearing its tissue, a certain quantity of thick, black blood escaped. In making a longitudinal section, a cavity as large as the fist was opened, filled with large, black clots. The pancreatic tissue was dark brown, and so softened and friable that it was impossible to determine the point of origin of the hemorrhage. The duct was moderately dilated, and the tissues in the immediate vicinity of the gland were strongly discolored with blood.

This case is not included among those of hemorrhagic pancreatitis, since the described appearances do not correspond with those usually found and the possibility of a pancreatic cyst or of an aneurism is not eliminated.

The following list of seventeen cases includes the instances of associated pancreatic hemorrhage and inflammation which present common features of symptoms and anatomical changes. Of these cases, three occurred within the vicinity of Boston; two of these are now, for the first time, reported, and the gross and microscopic specimens from the latter are submitted to your inspection.

[1] Deutsches Arch. f. klin. Med., 1875, xv. 455

[2] Bull. Soc. Med. de la Suisse Romande, 1877, xi. 345.

Case XVII.—Male, aged twenty-six. Strong. Drinks and smokes. Five years ago, from excesses, attacks of belching, nausea, cardialgia, colic, diarrhœa, burning sensation in upper abdomen. For sixteen days colicky attacks in upper abdomen, becoming more frequent. In past five days paroxysms have become more intense; nausea, vomiting, constipation, fever, anxiety, now collapsed. Burning, stabbing, griping pain from duodenum to spleen, toward navel, back and right shoulder, most severe along curvature of stomach. No stool for several days. Upper abdomen hot, swollen, sensitive. Death in eight hours. Pancreas doubled in size, firm, violet. Lobules much enlarged, dark, injected, interstitial tissue infiltrated with blood. Here and there in the blood, between the lobules, a finely granular, yellow exudation. Connective tissue around the pancreas swollen, friable, bluish-purple, infiltrated with blood.—Löschner. Weitenweber's *Beitr. z. Med.*, 1842; Schmidt's *Jahrb.*, 1843, xxxix. 31.

Case XVIII.—Male, young adult. Strong. Sudden cardialgia, without known cause, becoming violent on strong epigastric pressure. Constant bilious vomiting, obstinate constipation. High fever, quick pulse, collapse. Death in three days or more. No evidence of poisoning; diagnosis, perforating gastric ulcer. Pancreas at least doubled in size, dark-red. Hemorrhage between the lobules, and much extravasated blood in the vicinity of the pancreas, between the mesenteric folds.—Oppolzer. *Allg. Wien. med. Zeit.*, 1858, xlv.; *Mediz Neuigk.*, 1859, ix. 105; *Wien. med. Woch.*, 1867, vii. 7.

Case XIX.—Male, aged forty-four. Active, fat, florid, temperate. Sudden severe pain below left breast, nausea, constipation, tympanites, weak pulse. Second day, black vomit, dejection (alvine) exhaustion. Death in collapse on the third day. Pancreas enlarged, hard, friable, contained several small, scattered extravasations of blood. The seat of several lobules occupied by large lobules of fatty matter, from which much margarine crystallized out. Very many small granular cells in the interval between follicles.—Hooper. Beale's *Arch. of Med.*, 1860, ii. 282.

Case XX.—Male, aged thirty. Strongly built, fat, looked fond of spirits. In past few years frequent palpitation and occasional dyspnœa. Sudden abdominal fulness and tension attributed to new beer. Anxious, restless, uncomfortable. Feeble pulse, rapid breathing, cold sweat, subnormal temperature. Then abdominal pain, distended, tympanitic, upper abdomen. Nausea. Second day: collapse, spontaneous dejection, no fever. Sudden, violent delirium. Diagnosis: peritonitis from perforation. Death in thirty-six hours. Pancreas doubled in size, firm, dark violet. Extensive interlobular, hemorrhagic infiltration. In the head many nodular hemorrhages as large as cherry-stones, marked bloody infiltration of the peripancreatic tissue.—Hilty. *Corresp. Bl. f. Schweiz. Aerzte*, 1877, vii. 666.

Case XXI.—Male. Intemperate. In delirium tremens for a few days, then death. Pancreas trebled in size from presence of fat tissue within and around the gland. Minute hemorrhages in places. Microscopic examination showed hemorrhage between the cells, and a small-celled infiltration in the interstitial tissue. A peripancreatitis with gradual extension into the parenchyma.—Guillery. *Ueber d. Entz. d. Pankreas*, Inaug. Diss., 1879, 26.

Case XXII.—Male, aged forty-two. Fat, temperate. Has had repeated attacks of severe abdominal pain, with bilious vomit. Watery vomit every morning for some time, and before present attacks. Severe abdominal pain, worse in left side on palpation. No vomiting. Subnormal temperature. Abdomen tympanitic, distended, especially below navel. Second day: pain less, pulse weak. Death. In head of pancreas a cavity with butter-like contents. A hemorrhagic mass in the tail, apparently the starting-point of a peritonitis along the pancreas. Omentum thickly strewn with small, dirty

white, rounded, flattened patches, composed of cheesy, degenerated fat.—Farge. *Bull. Soc. de Méd.*, 1880–82, N. S. viii. 188.

Case XXIII.—Male, adult. Robust. Occasionally easily relieved, painful indigestion. A year ago jaundice lasting two and a half months, accompanied with some epigastric pain. Epigastric pain: unable to continue occupation. Second day: symptoms of peritonitis with great prostration. Death on the following day. Pancreas dirty red, containing brownish-black nodules, mottled with opaque-white spots. The microscope showed diffuse blood, and amorphous clumps of the same. The white spots due to short, staff, or spindle-shaped crystals in the fat tissue. Outline of gland cells lost, nuclei indistinct. Peritoneum reddened.—Whitney. *Boston Med. and Surg. Journ.*, 1881, cv. 592.

Case XXIV.—Male, aged fifty-four. Enormous quantity of subcutaneous fat. Sick for two or three days before death with slight gastric difficulties, soon followed by vomiting, symptoms of peritonitis, and collapse. Diagnosis: internal strangulation. Pancreas enlarged, soft, pale, dirty yellow, speckled with numerous opaque-white streaks and spots, also dark brown and reddish-black spots. Numerous ducts filled with blood-clots. Head of pancreas infiltrated with blood, and surrounded with clotted blood. Numerous hemorrhagic patches in the mesentery. Also opaque, bright yellow patches the size of a cherry-stone in the subperitoneal fat of the abdominal walls and in that of the omentum and mesentery.—Balser. Virchow's *Arch.*, 1882, xv. 525.

Case XXV.—Female, aged thirty-three. During first pregnancy much gastric disturbance and headache. In the last three months violent attacks of abdominal pain, suggesting impending perforation. Slow recovery. Two attacks during the five weeks after delivery. Sudden violent pain near pylorus thirty-seven days after delivery. Occasional vomiting, some collapse, no fever. Sensitive epigastrium, abdomen moderately distended. The violent epigastric pain persisted; meteorism took place. Collapse and death in five days. Pancreas enlarged, almost wholly transformed into a brownish-red, bloody mass. The microscope showed a small-celled infiltration and hemorrhage which may have continued for some days. Duct somewhat dilated. Adjacent omentum slightly suffused with blood.—Haidlen. *Cbl. f. Gyn.*, 1884, viii. 609.

Case XXVI.—The patient died of ileus. There was a hemorrhagic pancreatitis and peripancreatitis. The pancreas was as large round as a man's arm, and was so wedged between the spleen and the duodenum as completely to obstruct the latter.—Eichhorst. Eulenberg's *Real Encyclopædia*, 1885, ii. 434.

Case XXVII.—Male, adult. In perfect health. Sudden nausea, vomiting, and slight diarrhœa. Some hours later severe gastric and abdominal pains and cramps. Second day: pains more frequent, intense thirst, collapse, slight albuminuria. Third day: no dejection; subnormal temperature. Unexpected death on the fourth day. Pancreas enlarged, hard. Between it and the duodenum, encroaching on the former, but adherent to both, was a flattened mass of blood an inch and a half in diameter.—Amidon. *Boston Med. and Surg. Journ.*, 1886, cxv. 594.

Case XXVIII.—Male, aged forty. For a year or more general malaise and lack of strength, attributed to indigestion. Epigastric pain, vomiting, weak heart. Death on the sixth day, preceded by cessation of pain and vomiting. Pancreas very large, on section dark-red streaks and patches between the lobules. The fat tissue of the abdomen, especially near the pancreas, studded with opaque-white spots of fat necrosis, with a well-defined blackish edge. Colonies of micrococci found near these spots.—Pinkham and Whitney. MSS. Notes, 1886.

Case XXIX.—Male, aged fifty-eight. Intense epigastric pain for several days. Sensitive epigastrium, haggard, emaciated. Cancer of stomach suspected. Found asleep after breakfast with Cheyne-Stokes breathing, almost imperceptible pulse. Death in less than three hours after discovery in the above condition. Universal, interstitial, pancreatic hemorrhage, with clots in the tail. In the body of the gland the acini appeared as grayish-white areas surrounded by the dark red hemorrhagic exudation. Increased round-cells in the semilunar ganglia, whose ganglion-cells were cloudy and indistinct. Œdematous Pacinian corpuscles behind duodenum and pancreas.—Osler and Hughes. *Trans. of Phila. Path. Soc.*, 1888, xiii. 24.

Case XXX.—Female, aged fifty-six. Very fat. Attacked with vomiting, abdominal pain; complete obstruction. A swollen intestinal convolution to be felt in the right side. On the fourth day, sudden collapse, mind clear, abdomen distended, very painful, no palpable tumor. Laparotomy. Death five hours later. Pancreas greatly enlarged, black from hemorrhage, fatty degenerated. General peritonitis with adhesions and hemorrhagic exudation. Yellowish-white spots, up to the size of lentils, were seen beneath the parietal and visceral peritoneum, both at the operation and after death. They were composed of crystalline fatty acids, —Hirschberg. *Berliner klinische Wochenschrift*, 1887, xxxiv. 287.

Case XXXI.—Male, aged thirty-eight. Sudden, violent, colicky pains above the navel. Soon, high fever, delirium, copious green vomit, and death on the second day. Pancreas markedly enlarged, dirty, brownish-red color. On section, dirty, grayish-red plugs were squeezed from the lobes and lobules. The microscope showed the interstitial tissue infiltrated with round-cells and red blood-corpuscles. The epithelium enlarged, granular; in many acini transformed into a finely granular detritus; a bloody, ichorous fluid in the pancreatic duct. Considerable swelling, hyperæmia, and ecchymosis of the duodenum and jejunum.—Birch and Hirschfeld. *Lehrb. d. Path. Anatomie*, 3te Aufl., 1887, ii. 639.

Case XXXII.—Male, aged forty-two.—Birch and Hirschfeld. Op. cit.

Case XXXIII.—Male, aged forty-eight. Abundant fat-tissue. Hemiplegic for several years. Has had several attacks of gastric pain, not lasting more than a day. Awoke with severe gastralgia, vomiting, later collapsed. Second day: restless, but comfortable with morphia. Hiccough, vomited some dark red lumps. Third day: rapid breathing, cyanotic, collapse. Death. Pancreas doubled in size. On section, dark red, mottled with opaque-white spots. Fat tissue near pancreas and in root of mesentery discolored red. Mesenteric fat-tissue showed numerous opaque-white spots. The fat-tissue in places discolored, soft, and foul-smelling. Thrombosis of splenic, pancreatic, and mesenteric veins. No infiltration about semilunar ganglion.—Putnam and Whitney. MSS. Notes, 1888.

I am indebted to Drs. Pinkham and Whitney for their notes of Case XXVIII. The patient was a man, forty years of age, by occupation a caterer. He was liable to attacks of acute indigestion, and for a year or more before his death had suffered from general malaise and debility. His discomfort was attributed to indigestion. His last illness was of six days' duration and was characterized by epigastric pain, vomiting, and by great cardiac weakness. Death occurred from heart-failure after the pain and vomiting had ceased.

There was a large quantity of abdominal fat and the post-mortem examination was negative, with the exception of the appearances described below. The pancreas

was very large, weighing, with some adherent fat, four hundred and ten grammes. The cut surface showed everywhere dark red streaks and patches between the lobules and separating them to a slight degree. On microscopic examination there was no evident alteration of the gland-cells. A considerable quantity of free blood-corpuscles was found in the intralobular tissue. The fat tissue was everywhere filled with small, opaque-white spots, often with a well-defined, dark border. Their diameter varied from a few millimetres to several centimetres. They were present within the pancreatic fat-tissue and in that outside the organ. Microscopic examination showed that the fat-tissue was changed to a finely granular mass in which were numerous, very fine, acicular cystals. In the vicinity of the patches of necrotic fat-tissue were found colonies of micrococci.

For the purposes of this paper a more extended microscopical examination has been made of the above pancreas.[1]

There is an extensive inter- and intra-lobular infiltration of fat-tissue. The interlobular fibrous tissue is increased in places and the contained duct is widely dilated.

The pancreatic lobules are, at times, diffusely stained of a brownish-yellow color. Certain lobules contain clusters of orange-colored, acicular crystals, especially in the vicinity of the fat-tissue.

The interlobular fat-tissue shows circumscribed, as well as diffused, hemorrhagic infiltration. There is, in addition, an excessive accumulation of round cells, in places wholly cellular, again fibrino-cellular, entirely replacing the fat-tissue. There are sharply defined islets of fat-tissue in which the individual cells are indistinct, without nuclear staining, the whole filled with acicular fat-crystals. The border is often sharply defined by a zone, in which are small, round clumps of orange-colored, acicular crystals, and outside of which a line of round-celled accumulation is frequent. Bacterial clumps and venous thrombi are present.

The described changes in the interlobular fat-tissue are likewise seen in the parapancreatic fat. The following is the history of Case XXXIII., for the notes of which I am indebted to Drs. J. J. Putnam and Whitney. The patient was a gentleman, forty-eight years of age, who had been hemiplegic for several years. He was well-nourished, but not excessively fat. He had suffered from several attacks of pain in the region of the stomach, with chilly sensations, from which he recovered in the course of twenty-four hours. They were usually attributed to indigestion, but no exciting cause was ever discovered. He had one severe attack of this sort a year before his death, and became collapsed, and was covered with cold sweat. His mind was dulled and his talk somewhat incoherent. He rallied under the use of stimulants, and in the course of a day or two appeared in his usual health.

At 5 A. M. he was seized with a severe stomach-ache, and a few hours later vomited, with temporary relief to the pain. Throughout there was considerable dull epigastric pain, and occasional nausea and vomiting. In the evening, immediately after vomiting, he suddenly became collapsed. There was constant pain throughout the night, and restlessness. During the second day he improved somewhat, although annoyed by hiccough. He vomited chiefly mucus, in which were found several small, dark red lumps about the size of peas.

Early in the third day he was very restless, cold, and livid, his breathing rapid, and his pulse almost imperceptible. He was conscious but anxious, and died within six hours after the collapse became extreme.

The pancreas was about twice the normal size; on section, of a dark red color mottled with opaque-white spots and patches, which lay between the lobules of the gland. These changes were most marked in the body of the gland, the head being relatively normal. The fat-tissue near the pancreas, that in the root of the mesentery, and in the mesocolon near the spleen was of a dark red color. In places it was soft, discolored, and foul-smelling. Numerous opaque, grayish-white spots were visible beneath the mesenteric peritoneum. The splenic vein contained a soft, dark, adherent thrombus which was continued into some of the pancreatic veins. Recent thrombi were also found in some of the mesenteric veins. The spleen was slightly enlarged, the pulp increased and dark red.

There was no infiltration in the vicinity of the solar plexus and semilunar ganglion.

There was no evidence of a peritonitis.

In the microscopic examination of the hardened pancreas there is seen a sharp differentiation of the section into three zones.

The intermediary zone represents the interlobular fat-tissue which is continuous with that around the pancreas. It is not only extensively infiltrated with blood, but is often transformed into a porous structure from the apparent destruction of fat-cells. Elsewhere it contains a fibrillated meshwork, finely granular material, bacteria, and numbers of acicular fat-crystals. There is also an occasional round-celled infiltration of this fat tissue between the relatively normal portions of the pancreas and the hemorrhagic and necrotic interlobular fat-tissue.

On the one side of this intermediary zone the acini are distinctly defined and the nuclei clearly stained. Occasionally lobules are seen with granular epithelium and indistinct nuclei. There are, in places, an intra- and inter-lobular infiltration of blood-corpuscles and numerous accumulations of round cells. The interlobular tissue shows a fibrillated meshwork, apparently clotted fibrin; in the smaller ducts are numerous leucocytes.

On the other side of the hemorrhagic zone, although the lobules are distinct, the borders of the acini are often confused. The cells are granular, frequently not differentiated, and there is no staining of the nuclei. At times the lobules are replaced by a granular detritus or the cells are widely separated from each other. Here and there among these necrotic acini are stained islets, apparently bacterial colonies, thrombotic veins, and, more rarely, small accumulations of round cells.

At the edge of the pancreas is a large venous thrombus containing innumerable bacteria.

Of the seventeen cases of hemorrhagic pancreatitis, fourteen were males and two were females, the sex of one person not being stated. Their ages were as follows:

[1] Unless otherwise specified, the sections from the specimens hardened in alcohol are made with a microtome, stained in hæmatoxylin, carmine, or aniline blue or brown, dehydrated, and mounted in glycerine or balsam.

Years of age.	Number of cases.
From 25-30	1
" 30-35	2
" 35-40	1
" 40-45	4
" 45-50	1
" 50-55	1
" 55-60	2

One was described as a young adult, two as adults, and nothing was stated concerning the age of two.

The patients were usually in good health at the time of the attack, a few of them being conspicuously strong and robust. Nearly one-half of them were abundantly or superabundantly provided with fat tissue.

A small fraction, nearly one-sixth, was addicted to the abuse of alcohol. Nearly one-half of the cases suffered from previous attacks of indigestion.

These attacks were usually characterized by pain, which was colicky, gastric, or abdominal, and so severe in one instance as to suggest impending perforation. Vomiting, either watery or bilious, or both, was noted. Nausea, belching, and diarrhœa were recorded. Jaundice occurred in a single instance.

It is obvious from the above statement that the previous digestive disturbances were rather gastric or gastro-duodenal than enteric.

The immediate attack began, in the great majority of cases, with abdominal pain, usually without known cause, though rarely some irregularity in diet appears to have been an immediate predecessor. The pain was violent, intense, or severe, either constant or paroxysmal. Its seat was usually in the upper abdomen, and, in one instance, was stated to have followed the course of the pancreas; subsequently, in one-fifth of the cases, the abdominal pain became general.

The initial pain was usually followed by vomiting, more rarely by nausea alone. In one case there was a conspicuous record of no vomiting. The vomiting was constant, repeated, or occasional. It might be copious. It was bilious at times, or black, and contained, in one instance, dark red clumps the size of peas.

Constipation was a symptom of frequent occurrence and a diagnosis of intestinal obstruction was made in three instances, in one of which laparotomy was performed. The occurrence of diarrhœa was noted in but one case. Hiccough and albuminuria each were reported in a single case.

Fever was an inconstant symptom. When present it was of early occurrence, and might be high on the second day. On the contrary, the temperature might be normal on the first day and subnormal on the following day. Delirium was present in three cases.

A tympanitic swelling of the abdomen was of no infrequent occurrence. It was usually general, or in the upper abdomen, and was rarely localized in the lower abdomen. In one case, thought to be of intestinal obstruction, a swollen intestinal convolution was to be felt in the right side.

Symptoms of collapse were almost invariably present, and usually directly preceded death.

This occurred as follows:

On the 2d day in	3 cases.
" 3d "	5 "
" 4th "	3 "
" 5th "	1 case.
" 6th "	1 "

It took place after a few or several days, each in one case.

The diagnosis lay between intestinal obstruction, perforative peritonitis, and an irritant poison.

The pancreas was found enlarged, either throughout or at one extremity, usually at the head. The gland was frequently doubled in size, and might seem still larger when abundant fat-tissue was present. The enlargement has been compared to the size of a man's arm.

The gland was generally dense, sometimes friable, and has been noticed to be of diminished consistency.

The existence of hemorrhage was usually suspected by the appearance of the surface, which is of various shades of red. On section, however, the color may be dark-red, reddish-brown, violet, reddish-black, or even black. The modification in color may be uniformly distributed, or lie in patches or in specks. The patches correspond with nodules which may project above the surface. These discolored patches may show white specks or streaks, and the red color may lie in the interlobular tissue of the pancreas.

The color of the section may be affected by the presence of associated alterations, one of which is accidental, the other may be incidental. The former is due to an excessive quantity of fat-tissue in the pancreas, sometimes appearing to form nodules as large as hazel-nuts, and to treble the size of the gland. Bands and spots of a translucent yellow are thus produced which are mottled with shades of red. The incidental appearance is due to the presence of opaque-white specks, spots, and streaks, which are generally known, since the publication of Balser's[1] article, by the term fat-necrosis. These were seen in six of the cases, and it is not improbable that the granular exudation described by Löschner may have been of the same nature.

The pancreatic duct may contain a bloody, ichorous fluid, and its branches may be plugged with clotted blood. The duodenum and jejunum may show swelling, injection, and ecchymosis.

The hemorrhagic infiltration may be found beyond the pancreas, both in the parapancreatic tissue, mesentery, meso-colon, and in the omentum. It may extend downward behind the descending colon, nearly to Poupart's ligament, and may be found at the outer border of the left kidney.

The splenic artery and vein are usually free from changes. The latter may contain a thrombus. The portal vein has been found free from thrombosis.

The condition of the other organs is essentially negative.

The heart may contain liquid blood, or a differentiated clot may be found in the right ventricle.

The spleen may be small, with wrinkled capsule, or it may be slightly enlarged and injected.

The peritoneum usually shows no alterations, although evidence of recent peritonitis may, at times, be found.

The microscopical changes to be found in the diseased pancreas have been sufficiently detailed in the reports of Cases XXVIII. and XXXIII. They consist essentially in the evidence of an extensive, hemorrhagic infiltration limited more particularly to the interlobular tissue. Also in the presence of cellular and fibrino-cellular formations in the same tissue. Smaller accumulations of round cells and hemorrhages may be found within the lobules, and the ducts may be filled with indifferent

[1] Loc. cit.

cells. The appearances characteristic of a coagulation-necrosis, also thrombosis of the smaller veins, are to be found in many lobules as early as the third day, as are all the other changes above described. The spongy condition of the hemorrhagic region and the numbers of associated bacteria are indicative of putrefactive changes. Whether these are of ante- or post-mortem origin the evidence at hand does not decide. Finally, the discovery by Osler and Hughes[1] may be mentioned, where an increased number of leucocytes was found in the semilunar ganglia, and an indistinctness and cloudiness of the ganglion cells.

In summing up the clinical and anatomical characteristics of these cases we have the following brief description of an affection which wholly justifies the term acute hemorrhagic pancreatitis.

It is a disease which may take place without any well-defined cause, but is most likely to occur in persons who have had previous attacks of gastric or gastro-duodenal dyspepsia.

It begins with intense pain, especially in the upper abdomen, soon followed by vomiting, which is likely to be more or less obstinate, and, not infrequently, by slight, epigastric swelling and tenderness, with obstinate constipation.

A normal or subnormal temperature may be present and symptoms of collapse precede, by a few hours, death, which is most likely to occur between the second and fourth days.

The gross lesions are due to hemorrhage in and about the pancreas, and the microscope shows cellular and fibrino-cellular exudations in its interstitial tissue and necrosis of its lobules.

ACTINOMYCOSIS IN MAN, WITH THE REPORT OF A CASE.[2]

BY GEORGE A. BODAMER, M.D., B.S.,
PHYSICIAN IN CHIEF TO THE GERMAN HOSPITAL, PHILADELPHIA, ETC.

ALTHOUGH about forty-nine cases of actinomycosis in man have been recorded abroad, but four authenticated cases are found in American medical literature; these cases are two by Dr. Murphy, of Chicago (*N. Y. Medical Journal*, 1885, vol. xli. pp. 17–19); one by Dr. Schirmer (*Chicago Med. Journal and Examiner*, vol. liii. p. 354); and the last by Dr. Ochsner (*Ibid.*, vol. liii. pp. 1–3), to be quoted below. Hence I think the case which came under my observation worthy of record.

My investigations of actinomycosis in animals, which I made in 1883–84, at the Pathological Laboratory of the University of Pennsylvania, are about to be published in the *Journal of Comparative Anatomy and Surgery*. Since these investigations I have obtained several more cases in animals, making a total of ten cases.

My case of human actinomycosis is as follows:

Wm. M. H., aged thirty-two years. Born in England; occupation miner; mother, four brothers, and three sisters living and in good health; father died of senile debility. Patient had ordinary diseases of childhood, besides pleurisy at the age of twenty-eight years. He came to this country at the age of twenty-one years, and continued his occupation steadily as a miner, and he was often subjected to injuries of the head. In 1877 he was severely struck on the right side of the head by a prop. He continued to work in the mines, and while in the Stockton Coal Company's mines, Luzerne County, Pa., he noticed for the first time a swelling at the angle of the right inferior maxillary bone, which would go and come; and, as the patient expressed it, came to stay in the winter of 1882, and soon after reached the size of a chicken's egg, when he became alarmed, and began poulticing it; at the same time he had the three upper and three lower back molars of the right side drawn. All six teeth were sound.

Patient states he was advised to keep the gums bleeding and irritated, believing this treatment would reduce the swelling and effect a cure. A growth, however, promptly made its appearance, filling up the cavity made by the extraction of the teeth of the lower and upper jaws. About this time he ran against a projecting drill (an iron rod six feet in length with a sharp, square end two inches broad), which severely injured the tumor; the wound bled profusely but healed promptly.

During 1883 the swelling made little progress, and in May, 1884, he came to Philadelphia, and was admitted to the surgical wards of the Pennsylvania Hospital, where, as he states, a tumor was removed. He then returned to work, and had no

FIG. 1.

Case of actinomycosis.

medical treatment for four years, when he again entered the Pennsylvania Hospital in November, 1888,

[1] Case XXIX.

[2] Reported to the German Medical Society of Philadelphia, January 14, 1889, and to the Pathological Society, Jan. 24.

having in the meantime sustained some more injuries of the diseased jaw. There is no evidence that a diagnosis of actinomycosis had been made.

On Jan. 11, 1889, he came under my observation at the German Hospital, when I examined him in conjunction with Drs. John B. Deaver and F. Gross.

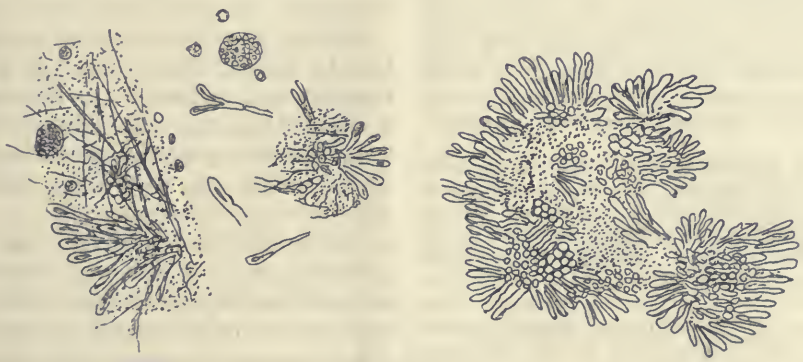
Present condition: Patient is a muscular, well-nourished, robust man, of five feet five and a half inches in height, with good complexion, weighing one hundred and fifty pounds, and has a good appetite. The only lesion observed is a swelling on the right side of the head, face, and neck (see Fig. 1, from a photograph) which consists of a hard, infiltrated, uniform mass, extending from the clavicle to the temporal region, involving the anterior half of the temporal muscle, the muscles of the face, and the glands of the neck, and evidently in intimate union with the cranial bones of the region described. The swelling implicates also the cavity of the mouth; the buccal muscles, as well as the lower and upper jaw, are much enlarged from the swelling, which causes an ankylosis, so that the patient cannot separate his teeth more than a quarter of an inch, and is unable to take food except by forcing it through this narrow space; this, the patient said, has been the case for the last two years. While mastication is next to impossible, the power of deglutition appears to be perfect. He uses mainly food in a crushed or liquid state.

The swelling is uniformly firm except in the temporal region, where there is a fistulous opening; another fistulous opening is at the angle of the jaw, but numerous scars upon the neck indicate that there were a number of fistulous openings which have healed. A third fistulous opening into the mouth corresponds to the third lower molar tooth. The patient states that there had been a great deal of suppuration from the former fistulas. On the whole, the right side of the head, face, and neck is about one inch thicker than the left side; the pain is slight, somewhat increased by pressure and is more intense during the night. A large scar extending from the angle of the mouth to the lower border of the inferior maxilla indicates a former removal of some of the tumor mass in 1884, at the Pennsylvania Hospital, as the patient states.

The discharge from the fistulous openings is sometimes copious, but at present not more than a few drops at a time; it consists of a purulent, odorless, viscid liquid of a grayish color, and suspended in it are numerous yellowish granules distinctly recognizable by the naked eye, being of the size of small poppy seeds. These granules I found under the microscope to be actinomyces, the radiating fungus peculiar to actinomycosis, and I diagnosed the case accordingly.

The fluid in which the fungus is suspended contains numerous compound granule cells, granular material, pus corpuscles, and fragments of fibres in a state of fatty metamorphosis; the fungus presents itself in its perfectly developed or adult form as radiating tufts, round or elongated, measuring $\frac{1}{200}$ to $\frac{1}{50}$ of an inch in diameter; the mycelia are unusually plain and single free mycelia or clusters of two and three, as I have seen in animal actinomycosis, are quite scarce (see Fig. 2).

Fig. 2.



Actinomyces.

The patient was operated upon by Dr. Deaver assisted by myself, Feb. 9, 1889. An exploratory incision being made from the fistulous opening in the temporal region to within one inch of the angle of the inferior maxilla and the skin which was involved dissected back, disclosed a very vascular infiltrated mass, fibroid in character, with actinomyces studded through its entirety; also two cavities one-half inch in diameter which contained material in a state of fatty metamorphosis which, under the microscope, revealed pus, compound granule cells, blood, oil globules, molecular débris, and the fungus actinomyces.

There was a profuse general oozing of blood over the whole surface of the exposed swelling. A sinus led from the fistulous opening in the temporal region down to the zygoma, which was necrosed, and beneath the same into the pterygo-maxillary region.

A part only of the tumor mass was removed, and the exposed growth was thoroughly curetted and irrigated with 1:1000 sublimate solution; a drainage tube was inserted, the skin adjusted and the wound dressed antiseptically.

The four cases of actinomycosis in man recorded previous to this case of mine are as follows:

Case I.—A female twenty-eight years old, suffered severe toothache of left lower jaw with subsequent swell-

ng in mouth and throat, the swelling (abscess in left tonsil) was opened and patient recovered rapidly. About seven months later, a swelling the size of a walnut appeared on the left side of the neck, which was lanced; the pus contained actinomyces. As the swelling and induration continued to increase, an operation was performed and the growth removed. Patient made a rapid recovery, gaining twenty-six pounds in five weeks and now (1885) is in good health.—Dr. Murphy, *New York Medical Journal*, 1885, vol. xli. p. 17.

CASE II.—Thomas C., aged eighteen, while in Ireland had severe toothache; later, a swelling appeared and enlarged with more or less pain; a carious tooth was found, a swelling was punctured, and a few drops of pus escaped which contained actinomyces; the sinus was scraped out and the parts completely healed. Later, a swelling reappeared in the same place which was opened and a drainage tube inserted, after which Dr. Murphy did not see the case, but heard that the opening healed. (Ibid.)

CASE III.—A Pole, twenty-five years of age, family history good. When eighteen years of age, while chopping wood, received a slight incised wound of cheek. Following this injury both jaws began to swell; the swelling in the left side disappeared and that on the right side was opened and a fistula followed. In June, 1886, patient passed into Dr. Schirmer's hands. The exudate from the fistulous opening was examined by Prof. Fenger and Dr. Schirmer; and actinomyces was found. Patient lost his appetite, became emaciated, followed by severe cough and the expectoration contained actinomyces.—Dr. Schirmer, *Chicago Medical Journal and Examiner*, vol. liii. p. 354.

CASE IV.—Man, aged fifty-six years, whose occupation was stock-raising and dealing, was much exposed to draughts and cold. He suffered pain in the left antrum of Highmore, and although he had six teeth drawn which were sound, no relief followed. For six months patient suffered excruciating pains in left antrum and both eyes. Early in 1878 there was a spontaneous opening of the abscess into the pharynx, from time to time evacuating considerable pus and blood; some of the discharge entered the larynx at night giving rise to severe cough. In 1880 was operated upon, curetting and irrigation of the parts resorted to; irrigation was kept up two years, patient suffering continuous pain. In 1885-86 severe cough with dulness over lungs, roughened respiratory sounds and mucous râles followed by great loss of weight. Microscopic examination of the sputum revealed actinomyces.—Dr. Ochsner, *Journal of Amer. Medical Association*, 1886, pp. 608-610; *Chicago Medical Journal and Examiner*, vol. liii., No. vi., pp. 1-3.

Lack of space will not permit me to refer to the European cases of human actinomycosis in the present article.

ON UNUSUAL METHODS OF ACQUIRING SYPHILIS, WITH REPORTS OF CASES.[1]

BY L. DUNCAN BULKLEY, A.M., M.D.,
OF NEW YORK.

THE subject which is indicated by the title of this paper is so vast, and relates to such a mass of facts recorded in literature, that it will not be possible to compass it at all completely, much less to consider exhaustively all the phases which it may present; indeed, the limits of the allotted time will permit of not more than a brief sketch of the general subject, and the elaboration of a few points, with the presentation of some illustrative cases.[1] The object of the paper is rather to call attention to the not infrequent acquiring of syphilis not only by means which are entirely innocent on the part of the sufferer, but also often in a manner wholly unexpected and generally quite unprovided against; it is also desired to provoke a discussion of the subject.

With the more general recognition of the non-venereal or innocent acquiring of syphilis, it will happen,

1st. That the dangers of the disease will be more widely recognized and guarded against, and so *fewer cases will occur.*

2d. Cases of syphilis will oftener be recognized when there is no history of venereal exposure.

3d. Less stigma will be attached to the disease, when it is well recognized that many acquire it innocently; and

4th. As a result of this last, syphilis may before long be placed, where it belongs, among the infectious diseases, under the care of health authorities; it is hoped that then something will be accomplished toward stamping out a malady which has already caused untold woe, both to the innocent and those guilty of sexual transgressions.

The general fact is already well known to the profession, in a general way, that syphilis is not always a venereal disease—that is, that it is not always acquired in impure sexual intercourse. But I think that the relative frequency of the different modes of infection is not sufficiently well known, and is not adequately considered in practice.

While syphilis still stands, as it has stood for many centuries, preëminently a venereal disease, the records of the past are very full of facts concerning its innocent transmission, and literature contains accounts of dozens of epidemics, large and small, involving thousands of persons who have acquired the disease innocently. There may also be found reports of individual cases, also aggregating thousands, where syphilis has been communicated by ways and methods which could hardly have been before suspected, and yet all in a perfectly innocent and unblamable manner.

It is not a little startling to hear so high an authority as Fournier declare, as he has recently done, from a careful study of his cases in private practice,[2] that in about twenty-five per cent. of all

[1] Read before the New York Academy of Medicine, January 17, 1889.

[1] It will also be impossible to present here the references to the various authors and writings on the subject, a full bibliography of which would occupy even more space than the article itself. These will be given later, in a fuller consideration of the subject.

[2] Fournier, Annales de Dermat. et de Syph., tome viii. No. 12, 1887, p. 757.

cases of syphilis in females, the disease is innocently and undeservedly acquired; and in the discussion on his paper, Ricord stated that his experience would fully corroborate the statement.

The proportion of cases of *syphilis insontium* in males is probably smaller than in females, but that the disease is not infrequently acquired by males in a most blameless manner is abundantly shown by a study of literature, and will also be seen by what shall follow.

In looking over the records of patients which have passed under my care in public and private practice, I find notes, more or less complete, of something over fifteen hundred individuals with syphilis. The larger share of these came under my care on account of skin lesions during the various periods of the disease, more commonly after the primary sore had disappeared, and in some instances even many years thereafter; and but a certain proportion of them came on account of the local sore, or even with its remains still present. In the greater number of instances no record whatever was made, either of the location or the character of the primary lesion, or of the source of infection, if, indeed, it was known to the patient or to myself. So that it is impossible to draw any definite conclusions in regard to the exact proportion of cases of *syphilis insontium* among them.

But among these fifteen hundred cases, notes of extra-genital chancres occur in sixty-six instances, or in 4.4 per cent. of all cases of syphilis; in most of these patients the sore was acquired in a perfectly innocent and unsuspected manner, quite unconnected with any venereal transgressions; of these sixty-six cases of extra-genital chancres, the larger number occurred in males, namely, thirty-four to thirty-two females.

Examining now more carefully the records of about four hundred cases of syphilis in private practice, I find that just one-third of all patients were females, and of these, over ten per cent. had hereditary syphilis; it further appears that in a very considerable share of the rest of the cases the disease was acquired in an innocent and perfectly unsuspected manner, generally from husbands, and in a number of unmarried females from lovers by means of kissing. It may be stated that in at least forty per cent. of the cases alluded to, of syphilis in females in the private practice of the writer, the evidence is as good as it is possible to furnish, that the disease was acquired innocently and undeservedly. Surely such an unnecessary amount of sickness and suffering calls for a consideration of the means by which it may be avoided.

Returning to the cases of extra-genital chancre before alluded to, they may be tabulated as follows:

PERSONAL CASES OF EXTRA-GENITAL CHANCRE.

Location.	Male.	Female	Total.
Chancre of the lip	13	18	31
" " finger	6	1	7
" " breast	—	6	6
" " tonsil	2	3	5
" " tongue	3	2	5
" " cheek	3	—	3
" " chin	1	1	2
" " eyelid	2	—	2
" " nose	1	—	1
" " ear	1	—	1
" " hand	—	1	1
" " forearm	1	—	1
" " sacral region	1	—	1
Grand total	34	32	66

Time will not permit here of a report of these cases in full, which will be given at a later date, as they are full of points of the greatest interest; some of the more important or peculiar cases will be mentioned later in the further illustration of our subject.

Turning now to the consideration of the "unusual methods of acquiring syphilis"—that is, by means other than by venereal contact—we find from a study of the thousands of cases recorded in literature, that the methods of transmission may be conveniently classed under three main groups, in each of which literally dozens of sub-groups, or separate modes of infection, may be made out; the limits of the paper permit of but the most brief allusion to the main groups, and some of the data falling under them.

Thus, non-venereal infection of syphilis may take place as:

I. *Syphilis economica*, where in the ordinary economic relations of domestic and industrial life the disease is transmitted, innocently, from one person to another.

II. *Syphilis brephotrophica*, where the disease is acquired by or from infants, in connection with their nourishment and care.

III. *Syphilis technica*, where the opportunity for the transference of the poison occurs in connection with various forms of body-service, medical and surgical, or of like nature.

We may now briefly consider a few of the details of these classes.

I. SYPHILIS ECONOMICA.

This is a very large class, and includes three main groups: 1, domestic transmission; 2, industrial transmission; and, 3, personal transmission.

1. *Domestic transmission.* All are familiar with many of the ordinary modes of the reported communication of syphilis by means of spoons, knives, forks, cups, glasses, and jugs. Tobacco pipes have been very frequently the means of carrying the infection, as has been repeatedly observed, especially in families or communities living rudely together, where one pipe may serve for several persons. In the fol-

lowing case, now under treatment for chancre on the lip, this seems to have been the method of communication:

CASE I.—Mr. F., aged fifty-one years, while living in a mining camp in California, received a blow on the under lip, in November, 1888, about six weeks previous to coming to the Skin and Cancer Hospital, January 2, 1889. The blow caused but little trouble, there being no outward injury, but only an abrasion within, caused by the patient's teeth. He was in the habit of smoking various pipes lying around in an assayer's office where he worked, resting the pipe on the affected lip, the action of sucking bringing the bruised part in contact with it. As some of the men frequenting the office were known to have sores in the mouth, it is supposed that the poison was readily conveyed on one or more of the pipes to the surface abraded by the injury. A week or two after the bruise the surface became again sore, and soon an induration appeared, and ten days later submaxillary adenopathy. The sore was cauterized several times, but failed to heal, and he came East for treatment.

When first seen the lesion was something over an inch in cross diameter, and occupied the inner half of the lip almost to the gum, in the centre; the raw surface secreted a glairy fluid, and induration was well marked. There were some general adenitis and a maculo-papular eruption, which had existed about a week. Under active antisyphilitic treatment the eruption soon disappeared and the sore healed.

Cigars have also been reported by several observers as a means of conveying the syphilitic poison, both after having been smoked by another, and also when fresh from the manufacturer. Some time ago[1] the writer reported two cases of chancre of the lip in physicians, where this appeared to be undoubtedly the mode in which infection occurred, and it is hardly necessary to repeat the observations here. Another case, less certain, has since been under observation and treatment.

Various articles of personal apparel, such as shirts, drawers, pantaloons, and handkerchiefs, have been known to transmit the syphilitic poison from one person to another, and the following interesting personal case shows how wearing of the article on a single occasion, in this instance a bathing suit, may suffice to inoculate the disease:

CASE II.—Mr. Y. E., aged forty-five years, a gentleman with a grown-up family, came to me on account of a diffuse maculo-papular syphilide, with general adenopathy. He was perfectly positive that he had had no venereal exposure in any manner whatever, and was shocked as well as indignant at the suggestion that he had syphilis, he having only very recently cautioned his son against sexual transgressions. He had no sore on the penis, and I searched a long time to find the site of entry of the poison, for the eruption was manifestly of such a recent syphilis that I felt confident that the chancre, or its well-marked remains, must be still present. The lips and cavity of the mouth were examined in vain, as also the fingers and all other portions of the body where one might expect to find such a sore.

On questioning still further as to whether he had not had some ulcerating spot on any portion of the body, he then called my attention to the sacral region, where he said that he had had a raw point for a number of weeks, which had been regarded as a simple ulcer, or as an epithelioma, by his family physician; it had, however, been suspected to be a chancre by a surgeon in another city, just before his visit, and just after the eruption appeared.

On examining the region, there was found an ulcer, deep in the fold of the nates, about an inch behind the anus, which, when the parts were separated, presented a round, ulcerated surface, about half an inch in diameter, sharply defined and with a grayish-white base; a distinct hardness could easily be made out on careful palpation.

The supposed and probable mode of infection was very interesting. He had long had some itching in that region, even for years, and at times a fissure would form along the crack of the nates, which, he said, existed also just before the new lesion developed. Some six weeks before his visit he had been in bathing, and, quite contrary to his usual custom, he had worn a strange suit of bathing clothes, and on account of the itching in that region he had rubbed and scratched the part vigorously through the bathing trowsers; the sore developed a few weeks after this single wearing of the public bathing suit at Coney Island. It is easy to understand how a previous bather with mucous patches at the anus had left the secretions on the garment, and the exertions of rubbing the dampened cloth upon the fissure readily afforded the best possible opportunity for infection. The patient suffered from a pretty severe attack of syphilis.

Similar cases have been reported where the disease was communicated to the region of the anus by wearing the clothes of others.

In addition to wearing apparel, cases are on record where the poison has been conveyed on bedding and toilet articles, sponges, combs, toothbrushes, and syringes; a case is also reported where an opera glass served as the conveyer of the virus, and Otis mentions a cane as a bearer of syphilitic contagion.

In the following case of chancre of the tongue, now under treatment, it seemed more than likely that the infection took place by means of pins, which the girl was in the habit of putting in the mouth, and carrying them just in the site where the chancre appeared.

CASE III.—Miss A. A., an intelligent and modest girl, aged twenty-five, a saleslady in one of the large Sixth Avenue variety stores, noticed a small ulceration of the left side of the tongue about six weeks previous to her first visit, October 31, 1888; the glands beneath the jaw on that side began to swell two or three weeks later. When first seen there was

[1] Archives of Dermatology, 1879, vol. v. p. 343.

a small induration at the left side of the tip of the tongue, with a fissure through its centre; beneath the tongue there were a few mucous patches. Under a soothing treatment the soreness increased, and the swelling and hardness augmented, until three weeks later it was the size of a hazelnut; talking and eating were decidedly painful, and mucous patches had developed in the throat; the submaxillary glands also increased much in size. She was then placed under antisyphilitic treatment, and at the present time the size and hardness of the lump have greatly diminished, as also the adenopathy. She has had very little eruption, except about the mouth, where a very characteristic flat papular syphilide still exists, rebellious to treatment, with occasional mucous patches.

After repeated questioning of her alone, I could not discover that she had been in any way exposed to syphilis; she lived quietly at home, and had no intimate gentleman acquaintances. I was led, therefore, to accept the probability that the poison was conveyed by means of pins which injured and inoculated the tongue, as she was in the habit of placing them in that side of the mouth, regardless of where she had obtained them.

Lint and plaster have also served to convey the syphilitic poison from one person to another, and a physician once told me that he had seen a patient in whom he believed the disease to have been received by means of caustic used on a former syphilitic sore; it is not supposed that the caustic itself could convey the virus, which it would naturally destroy, but probably, as he believed, the virus had adhered to the caustic-holder in which the short bit of nitrate of silver had been inserted.

It is a little remarkable that after a very considerable search I have failed to find in journal or other literature a single authenticated case where syphilis has been acquired from privy seats and public urinals, which are popularly supposed to be a fruitful source of innocent infection; the matter is scarcely alluded to seriously by any writers, a striking illustration of the fallacy of popular impressions or beliefs.

2. *Industrial transmission.* The next sub-group of *syphilis economica* is that where the poison is acquired in *industrial transmission*, during or by means of various trades and occupations. This includes a large class of cases, many of which are recognized by everyone. Thus, the well-known glass-blower's syphilis has in times past been conveyed to many individuals by means of a common pipe employed; several small epidemics of this are reported, especially in France, and I have been able to collect a total of one hundred and sixty-two cases in which syphilis has been acquired in this manner. At one time, when from twelve to fifteen men were thus infected in one factory, five or six of their wives received the disease innocently, besides many children. Assayers and goldsmiths have also been thus affected from a blowpipe used in common, and an instance is reported where the entire family of a weaver received infection through a pipe in the mouth used to sprinkle cloth.

Musicians have acquired the disease through wind instruments, and a car conductor from a whistle borrowed from a syphilitic friend. In one instance, three furriers received the disease by means of a thread drawn through the lips and bitten off, and tack nails passed from one mouth to another have also communicated the disease. Pens, pencils, paper-cutters, and lip glue have all been the means of transmitting syphilis, and in a single instance, not very well authenticated, a coin is said to have been the means of conveying the disease. It is not a little remarkable that not even an alleged case has been found where paper money has been the medium of infection, considering the condition of many bank notes and the frequent habit of wetting the finger when handling them. A recent journal has suggested a danger attendant on wetting postage-stamps on the lips, especially such as had been previously wet and partially attached to a letter for return postage; but no case illustrating this has been found in literature.

It is commonly supposed that laundresses are greatly exposed in washing for syphilitic subjects, but the instances on record where this is believed to have occurred are very rare, and some of these very dubious. The soaking and frequent boiling of the clothes, together with the soap used, suffice to dilute and kill the poison, and the constant placing of the hands in the water renders absorption difficult.

3. *Personal transmission.* The next sub-group of this class, namely, that of *personal transmission* by innocent means, covers but few varieties, but includes very many cases where the poison is acquired by means of kissing, biting, and during other non-venereal relations. Next to the venereal act, kissing probably now affords a larger proportion of cases of syphilis than any other mode of transmission, and hundreds of instances from this cause may be found reported. Among the sixty-five personal cases of extra-genital chancre alluded to previously, no less than thirty, or nearly one-half, were on the lips; among them were a little girl, four-and-a-half years old, and another, eleven years old, infected the one by the mother and the other by the father. There were several ladies infected by their lovers before marriage, and in the two following cases the poison was received, the one on the tonsil, and the other on the lip, both from the same man, who also came later under my care, and who married the second lady.

Case IV.—X. T., a most estimable young lady, aged thirty-two, had one of the most violent attacks of syphilis which I have ever witnessed, lasting over

years, and producing serious later results, owing in part to imperfect treatment, as she lived some distance from the city. She came to me during an early general papular syphilitic eruption, with a chancre of the right tonsil of two months and a half duration. There was a considerable flat excavation of the tonsil, with decided hardness, and sub-maxillary adenopathy of that side. After the patient whose case is next narrated and her husband both came under my care, I found, on comparing dates, that he had been engaged to the first young lady during the very active stage of his syphilis, when the mouth was full of lesions, and that when the nature of the disease and its source were discovered, the engagement was broken off, and he very shortly became engaged to the next case, to whom he gave a chancre of the lip just after marriage.

CASE V.—Mrs. Z. G., aged twenty-four, became engaged to the gentleman above referred to shortly after his former engagement had been broken, and was married soon thereafter. Almost immediately after marriage a sore appeared on the lower lip which refused to heal, lasting two months, and was shortly accompanied by a general rash, loss of hair, bone pains, and general malaise. Later, she had a tubercular syphilide and recurrent nodes on different parts of the body. Her husband came under my care for a while somewhat later, with bone-syphilis, and died subsequently in another city from kidney disease, which I had recognized as being probably syphilitic.

The following case of chancre of the lip is interesting, for the reason that the disease was contracted, not from a husband or lover, but from a female friend, who was also under my treatment for syphilis.

CASE VI.—Mrs. Y. F., aged twenty-six, lost her husband two months previous to her first visit. About the time of his death, and thereafter, she had much to do with a patient who was also under treatment at the Hospital, with a large papular syphilide of the forehead and cheeks and mucous patches on the lips and tongue. In her grief she kissed her friend repeatedly, and as a result came with a large chancre on the left side of the upper lip, which was followed by the development of full constitutional syphilis. When first seen, the sore was about three-quarters of an inch in diameter, circular, elevated, and with a distinctly sclerotic base; the submaxillary glands of the left side were also enlarged.

Biting and tooth wounds are also not infrequently followed by syphilitic inoculation, and a case is on record where the disease was communicated intentionally by a bite, the giver being actuated by personal spite and hatred.

The following case illustrates the difficulties sometimes attending the diagnosis of such cases:

CASE VII.—Y. A., a printer, aged thirty-three, applied for the treatment of a greatly inflamed ear, which had been torn in a fight three weeks previous to his visit, it having probably been bitten. The surface had been much irritated by basilicon ointment and other applications, and when first seen the entire left auricle was greatly inflamed and covered with a dried, crusted exudation; the diagnosis of simple dermatitis was made, and palliative and soothing treatment adopted. Two weeks later it was recorded that the lesion had spread greatly, and then occupied a space three inches long by two wide, in front of and on the ear, extending down to the lobule. The surface was ulcerated and irregularly elevated, with considerable tumefaction of the edge; the ulcerative process extended on to the ear, and occluded the auditory meatus. The pain in the sore was very great, especially at night; mild, non-specific treatment was still continued. One week later the surface was suppurating freely, with florid granulations, and the pain was still intense at night, abating toward morning. The diagnosis of probable chancre was now made, and the former treatment stopped; a mild calomel ointment was applied, and mixed treatment given internally, with a mercurial purge. The ulcer improved almost immediately, and healed with remarkable rapidity. Some moderate hardness of the edges developed during healing. Just before it healed a large papular syphilide appeared, and, later, mucous patches, bone pains, and other syphilitic symptoms completed the history of constitutional syphilis.

In addition to kissing and biting, there belong in this class those cases where syphilis has been communicated from one person to another by scratching and pinching, also certain others where the disease has been acquired innocently, on other parts than the genital regions, by contact in bed with syphilitic individuals; likewise some others where contact in carrying a person has afforded the means of entrance for the syphilitic poison.

(*To be concluded.*)

THE TREATMENT OF ARRESTED RESPIRATION IN ANÆSTHESIA.

BY EDWARD MARTIN, M.D.,
INSTRUCTOR IN SURGERY, UNIVERSITY OF PENNSYLVANIA; SURGEON TO THE PHILADELPHIA HOSPITAL AND TO THE HOWARD HOSPITAL;

AND

H. A. HARE, M.D.,
DEMONSTRATOR OF THERAPEUTICS AND INSTRUCTOR IN PHYSICAL DIAGNOSIS IN THE MEDICAL DEPARTMENT, AND IN PHYSIOLOGY IN THE BIOLOGICAL DEPARTMENT, UNIVERSITY OF PENNSYLVANIA.

IN a paper read before the Medical Society of London, Dr. Benjamin Howard maintains the following propositions:

1. The epiglottis falls backward in apnœa and closes the glottis; the first thing in order and importance is the elevation of the epiglottis.

2. Traction upon the tongue, however, and whatever the force employed, does not and cannot raise the epiglottis, as supposed.

3. The epiglottis can only be raised by extension of the head and neck.

4. The full effect of extension can only be secured with certainty by making the extension complete, as directed.

5. The method of making extension is as follows: "Having, by bringing the patient to the edge of the table or bed, or by elevation of the chest, provided that the head may swing quite free, with one hand under the chin and the other on the vertex, steadily but firmly carry the head backward and downward; the neck will share the motion, which must be continued till the utmost possible extension of both head and neck are obtained. Sometimes a slight elevation and extension of the chin will at once check stertor or irregularity of breathing; but understand, the extension which can in no case do harm, should always be rather more than appears necessary. It should never be forgotten, however, that the full effects of extension, as above described, can be secured with certainty only by making the extension complete as directed."

These propositions are, in some respects, so contrary to the daily experience of surgeons and anæsthetizers, and, if well founded, are of such supreme importance in cases of suspended, animation that we have conducted a series of experiments designed to test, in so far as this is possible by working upon the dead body, the validity of Howard's conclusions.

Limiting our inquiry to those cases of threatened death which occur from respiratory obstruction during the administration of an anæsthetic, we must first endeavor to discover the mechanical cause which is principally operative in producing such obstruction. We presume that by apnœa, Howard means, not a condition of suspended respiratory efforts through hyperoxidation of the blood, which is the true significance of the term, but cessation of respiratory movement. We cannot believe the epiglottis is chiefly at fault as an obstructive agent because, in the vast majority of cases, the air-passage is at once made free by drawing the tongue forward; since tip-traction has no effect upon the epiglottis, as stated by Howard and confirmed by our own observations, this manipulation could not relieve the breathing were the epiglottis the cause of the difficulty. The effect of traction upon the tip of the tongue is to draw this organ free from the soft palate and the post-pharyngeal wall; it is the tongue then, fallen back upon the posterior wall of the pharynx, which is the most common obstructing cause, consequently the tongue should receive the most immediate consideration. We do not for a moment deny the possibility of respiratory difficulty being caused by the epiglottis alone, though experimentally the inward passage of air was very little influenced by any position of the epiglottis, provided the tongue was carried well forward; we would insist, however, upon the position of the tongue as a matter of prime importance. Considering next the effect of tongue-traction upon the epiglottis, we are not prepared fully to endorse Howard's statement. Tip-traction moves the epiglottis not at all; this we have confirmed by many trials, both in the living and in the dead subject; but if a tenaculum is fixed in the dorsum of the tongue, two and a half inches back from the tip, traction at once draws the base of the tongue and the epiglottis with it, far forward, so that the air-passage is absolutely free, from the larynx to the mouth. Traction can, then, be so applied to the tongue that the epiglottis is raised, and the air-way made absolutely free, and we have devised an instument by which this may be accomplished without the laceration attendant on the use of hooks or forceps.

Is extension of the head and neck the only method of raising the epiglottis? Again we are compelled to take exception to Howard's statement. As detailed in our experiments, the epiglottis can be raised by traction upon the dorsum of the tongue, by pressing the greater cornua of the hyoid bone forward, by the action of gravity in the abdominal decubitus, and most thoroughly by flexing the neck and extending the head upon the neck. That Howard's position accomplishes mechanically all that he claims for it, we freely grant. The way in which the soft, collapsed structures straighten under his manipulation, the tongue riding forward, and the epiglottis springing erect, is most striking; and we are convinced that the admirable mechanical explanation he gives for this effect is correct. Howard states:

" . . . by extension of the head and neck, carried to the utmost completeness, the backward fallen tongue, the velum palati, and uvula are all simultaneously shifted from the air-way, and the entire pharynx is enlarged throughout, as follows: *a*. The tongue, the dorsum of which before fell by gravitation upon the then horizontal posterior wall of the pharynx, falls upon the now horizontal arch of the palate. *b*. The velum palati, by means of the great tension of the palato-pharyngei muscles, is pulled away from the posterior wall of the pharynx, the entire membrane being stretched tightly forward and downward behind part of the dorsum of the tongue, forming a partition which helps to shut the tongue out of the pharynx and into the mouth, where it belongs, and with part of the dorsum forms the anterior wall of a new post-oral air-way, thus created and maintained. *c*. The pharynx, anteriorly, is stretched far forward by the extremely tense sterno-thyroidei muscles acting through the thyroid cartilage, by the genio-hyoidei and mylo-hyoidei muscles acting through the os hyoidei. The base of the tongue and the velum palati are shifted forward in the manner already described, the posterior nares being shifted by the extension of the head by its occipito-vertebral articulation about sixty degrees. Posteriorly, the wall of the pharynx is shifted back its whole length by the extension of the cervical vertebræ upon each other, in all about thirty degrees, extension being particularly great just opposite the glottis. Thus the upper air-way, which before was a tortuous, angular, flaccid canal,—barely and, if at all,

uncertainly permeable,—is made an enlarged, firm, but slightly curved tube, free throughout, from the glottis to the nares."

With all this, except the backward shifting of the posterior wall of the pharynx by extension, we are fully in accord. We cannot, however, concede that his practical deduction from these facts is a step in the right direction. With the head and neck in extreme extension, the soft palate is strapped over the dorsum of the tongue, the mouth is closed from the pharynx, and the entrance of air to the lungs depends absolutely upon the condition of the nostrils. Can it be considered an additional safeguard, an improved method, to substitute for the roomy mouth, an air-way but just sufficient at the best, subject to an infinite variety of obstructions, varying in size from hour to hour, in many persons absolutely and permanently occluded? Certainly no American rhinologist would answer in the affirmative. Hypertrophies, polypoid growths, and vegetations are not the rare exception. The slightest congestion is frequently sufficient to block patulous nares. A nostril which will admit the little finger of the surgeon when the patient is standing, may become completely closed when the head is placed on a level with the body. The recumbent or dependent position, the irritating effect of ether upon the mucous membranes, cephalic congestion due to insufficient oxidation, all combine to render the nostrils unsafe—in fact, absolutely impracticable—as the sole passage of communication between the lungs and the external air. We cannot believe that recourse to this method, in cases of suspended animation under anæsthetics, could be followed by favorable results; if the tongue were drawn forward, it would certainly provide ample air-way, the passage from the pharynx to the mouth being opened by this manipulation. One of the great advantages of this method, however, as claimed by Howard, is that the necessity for traction upon the tongue is entirely done away with. If the necessity for drawing forward the tongue is not done away with, we cannot see that Howard's method offers any material advantage over that ordinarily practised in this city.

Our experiments show that extension of the head carried so far that the base-line (Reid's) makes an angle of somewhat more than fifty degrees to the plane of the bed or table, raises the tongue and epiglottis so entirely clear of the posterior pharynx that there is ample air-way; the soft palate too lies free of the post-pharyngeal wall, but is not drawn closely across the dorsum of the tongue, thus allowing respiration to take place through the mouth. If, in the course of an anæsthetization there is respiratory difficulty, the method which obtains here is as follows: The chin is immediately pressed forward by the fingers placed behind the rami of the lower jaw, at the same time and by the same manipulation the head is extended, the pillow, if any has been used, being removed; if there is still apparent obstruction, the tongue is now drawn forward. With this manipulation, except in case of foreign body or abnormality of structure, the air-passage from the mouth to the larynx is absolutely free. Hereafter we may modify this method, so placing the pillow that the neck is flexed as far forward as possible, then extending the head upon the neck, as we find that this gives us wide dilatation, the posterior pharyngeal wall representing the arc of a circle, from the concavity of which extension of the head draws forward the tongue, epiglottis, and larynx. In the method as detailed above, it rarely occurs that the tongue has to be drawn forward.

Finally, we cannot grant that Howard is justified in believing, of the hundred cases of death due to the administration of an anæsthetic, that in each case the epiglottis was in all probability unraised and continued unraised until death was complete. The appearance of the parts after death cannot be taken as indicative of their relative position during life—when inspiratory efforts are still taking place, when the rigor mortis has not made the surrounding muscles more rigid than the epiglottis. Again, the very traction upon the tongue, as usually exerted, extends the head sufficiently to carry the epiglottis free of the post-pharyngeal wall. Finally, where inspiratory efforts are being made there is no difficulty in determining whether or not air is entering the chest, the noise of its passage through the mouth and throat, the respiratory sounds, is sufficiently characteristic of its free entrance; while sinking in of the intercostal spaces, epigastrium, and suprasternal region during an inspiratory effort are absolutely diagnostic of obstruction. These signs, though not so patent, are still sufficiently clear in artificial respiration, and if the cause of death were even in the majority of cases simply obstructive, this condition of obstruction would unquestionably have been recognized and remedied, if not by position, certainly by tracheotomy or intubation.

The results of our examinations, made upon several cadavers, are as follows.

By chipping away the basilar process of the occipital bone the naso-pharynx is exposed.

Subject in the dorsal decubitus, head midway between flexion and extension, eyes looking directly upward, Reid's base-line (from the lower border of the orbit through the bony meatus) at right angles to the plane of the table.

The tongue lies in close contact with the posterior wall of the pharynx, only the tip of the epiglottis being visible. The soft palate and the dorsum of the tongue shut the mouth from the pharynx. The air-passage is completely obstructed by the tongue and epiglottis.

By means of a tenaculum passed through its tip

the tongue is seized and drawn forward as far as possible. The body of the tongue is drawn clear of the post-pharyngeal wall and the soft palate, but the hyoid bone, the base of the tongue, and the epiglottis, are influenced not at all.

The tenaculum is now fixed two and a half inches from the tip; traction draws both the base of the tongue and the epiglottis well forward.

The fingers are passed behind the angles of the lower jaw, and the latter is pressed forward; this elevates the epiglottis and the base of the tongue about a quarter of an inch from the post-pharyngeal wall. Extending the head so that the base-line makes an angle of forty-five degrees with the plane of the table, draws the base of the tongue and the hyoid bone far forward, this motion being at the same time imparted to the epiglottis, so that the latter stands upright and is separated from the posterior wall of the pharynx by an interval of about an inch. By tightly closing the jaw the antero-posterior space is still further increased.

The body is drawn to the end of the table so that the head hangs free, the latter is now extended till the base-line is parallel to the plane of the table, the antero-posterior space between epiglottis and pharynx is slightly greater than that which obtains from moderate extension. At the same time, the tongue drops toward the roof of the mouth, the soft palate is put upon the stretch, and the mouth cavity is shut out from that of the pharynx.

Placing the head so that the base-line is perpendicular to the plane of the table again produces complete closure of the pharynx, owing to the tongue and epiglottis falling directly backward.

Placing the fingers upon the posterior cornua of the hyoid bone and pressing the latter directly forward carries the epiglottis and tongue about one-half inch forward, and entirely free of the post-paryngeal wall.

With the head moderately extended and the jaw pushed forward an effort is made to crowd the tongue and epiglottis against the post-pharyngeal wall; this is found to be impossible.

Flexing the neck by lifting the head forward (keeping the base-line perpendicular to the plane of the table) separates the post-pharynx from the epiglottis and the base of the tongue by about one-half an inch. Extending the head upon the neck, the neck being still flexed, produces a yet wider separation, the antero-posterior diameter of the breathing space being somewhat more than one inch.

Placing the body in the position of abdominal decubitus, the base-line being perpendicular to the plane of the table, the hyoid bone, base of the tongue, and epiglottis all fall forward, leaving an interval of about a half inch between the epiglottis and post-pharyngeal wall.

On elevating the shoulders, by seizing them and lifting them directly upward, this space is increased to fully an inch; at the same time the arytenoid cartilages are drawn backward, exposing the glottis throughout its whole extent.

Bringing the body to the end of the table and letting the head droop forward (still in abdominal decubitus), thus flexing the neck to its full capacity, then extending the head at the occipito-atloid articulation, exposes the larynx more completely than any of the previous postures or manipulations.

Conclusions.—The epiglottis may prevent free entrance of air to the lungs even though the tongue is pulled forward. Any means which accomplishes the anterior projection of the hyoid bone immediately and infallibly raises the epiglottis and the base of the tongue.

The hyoid bone may be made to project anteriorly by direct pressure upon its cornua, by direct pressure or traction applied to the dorsum of the tongue behind the anterior half arches of the palate, by the action of gravity in the abdominal decubitus, or by extension of the head upon the neck.

Extension of the head upon the neck carried as far as forty-five degrees produces practically as patulous a condition of the air-way as forced and extreme extension. At the same time this moderate extension usually leaves sufficient room between the palate and the dorsum of the tongue for breathing to continue through the mouth.

In forced extension of the head and neck the entrance of air into the lungs depends upon the sufficiency of the nasal passages.

Flexion of the neck with extension of the head upon the neck does away with the epiglottis as an obstructing factor as completely as any other posture. This is best accomplished by supporting the head upon a high pillow, then pulling it directly backward by the hand placed under the chin, so that the weight of the head falls upon the occiput rather than upon the back of the neck.

Therefore, in case of an urgent respiratory crisis in anæsthetization we would direct that the index fingers placed behind the greater cornua of the hyoid bone, and the middle fingers resting upon the angles of the lower jaw, both these structures can be pressed directly forward, the same force also serving to extend the head upon the neck. If obstruction to breathing still persists, the tongue should be at once drawn or pushed forward by force exerted upon its dorsum posterior to the anterior half arches.

No force unless directly applied to the tongue itself is sufficient to infallibly prevent this organ from acting as an obstructing factor. No manipulation yet devised can, in every case, take the place of direct action.

The tongue may act either in conjunction with the pharyngeal walls or with the palate in prevent-

ing free entrance of air. If the position of moderate extension and direct traction or pressure upon the tongue fail to remove the obstruction to breathing, intubation or bronchotomy remains as the last resort.

MEDICAL PROGRESS.

Secondary Resection of Large Intestine after Gangrene.—MR. J. M. COTTERILL brought a most interesting case before the Medico-Chirurgical Society of Edinburgh in December last. An extremely stout woman, aged thirty-eight, was admitted with strangulated umbilical hernia into the Edinburgh Infirmary on April 14, 1888. The woman, who was pregnant (seven months), had had umbilical hernia for seven years, but the recent symptoms commenced after a slip in walking, about ten days before admission. She had not vomited during this time, and only did so once after she entered the infirmary. Her pulse and temperature were rising. Fifteen inches of gangrenous colon with gangrenous omentum were removed, and the cut edges stitched to the abdominal wound, the parts which had been in contact with extravasated fecal matter being carefully cleansed by a perchloride solution. The patient suffered severely from the effects of the operation, miscarried on the third day, losing much blood, then improved until the sixth day, when, after a severe rigor, she developed phlegmasia dolens of the right and then of the left leg. She made a good recovery, and, after three months' stay at home, returned with a request that the artificial anus might be operated upon, as she suffered great discomfort from it. For ten days before the operation of resection of the intestine she was fed on peptonized fluids, partly by mouth and partly by enema. Castor oil and enemata were frequently used to keep the bowels well cleared.

The operation, performed on September 20th, presented difficulty from the contracted condition of the lower end of the colon. The ends were carefully freed and washed. A piece of thin rubber tubing was passed around the gut through a small hole in the mesentery, and four inches removed from the upper and three from the lower end of the gut. Czerny's method of suturing was employed, and over one hundred stitches put in, in a double row; the cut edges of the mesentery were then sutured, and the gut replaced in the abdominal cavity. Some fever and restlessness followed, but the patient passed flatus next day, and a liquid motion the day after. Peptonized fluids were alone given for three weeks after the operation; the diet was then improved, and she left the infirmary cured on November 25th. Mr. Cotterill recommended in such cases the performance of an artificial anus, and later resection, and referred to the tables given by Mr. Makins, and to successful cases by Messrs. Hardie, Kendal Franks, and Weir.—*Lancet*, February 9, 1889.

The Earliest Symptoms of Inherited Syphilis.—DR. MILLER, of Moscow, bases the following remarks on the observation of one thousand cases of inherited syphilis. The first symptoms of the disease appeared during the first month after birth in 64 per cent., and during the second month in 22 per cent.; in 24 per cent. of the whole number of cases the outbreak occurred during the third week. The earliest symptoms were rhinitis and pemphigus; the former was noted in 58 per cent., and the latter in 25 per cent. of all the cases. The author attributed the coryza in many cases to the influence of cold, and does not consider this sign specific of itself. Syphilitic pemphigus is either present at birth or appears during the first, or, at latest, during the second week after birth, while idiopathic and cachectic pemphigus does not occur before the second or third week. Congenital syphilitic pneumonia was very rare (one or two per cent.). The presence of this affection is of no assistance, from a diagnostic point of view, as it cannot be distinguished from congenital atelectasis. Desquamation of the skin is not peculiar to syphilis, nor are aphthæ, which often form superficial and sometimes deep ulcers. Rhagades of the lips, especially of the upper lip, are very characteristic. Craniomalacia has nothing to do with syphilis, and swelling of the lymphatic glands is not part of the disease. Maculæ and papules were the commonest affections of the skin. Papules were observed in 74 per cent. of the whole number of cases, and in 24 per cent. of these the papules were the first sign of syphilis. Maculæ alone were found in 45 per cent., and in 17.9 per cent. of these as the first sign of the disease; but a mixture of maculæ and papules was the most frequent form of eruption (46 per cent.). The rarer manifestations of inherited syphilis are only briefly noticed in the paper. —*London Medical Recorder*, January 21, 1889.

Uses of Boracic Acid.—DR. LEBOVICZ, in the *Wiener med. Presse*, narrates some uses to which he has put boracic acid.

1. Boracic acid acts antiseptically. Every soldier should carry one ounce of it in his overcoat pocket, and a handkerchief cut into two triangles for necessary bandages. Simply sprinkling a wound with finely powdered boracic acid suffices to insure rapid healing. This remedy being odorless and itself absorbing all odors, the author has used it advantageously in abscesses, ulcers of the feet, caries and necrosis of the bones, and in complicated fractures.

2. In anthrax and after the incision of furuncles it acts well when applied directly to the parts. Forming furuncles should be painted several times daily with the following:

℞.—Boracic acid } . . āā equal parts.
Water }

3. In burns, when the flesh is exposed, it is necessary to be careful with poisonous antiseptics. Boracic acid possesses the advantage of being non-poisonous. He covers the burnt surfaces with a boracic vaseline ointment in the proportion of one to five:

℞.—Boracic acid (finely powdered) 20 parts.
Glycerine . . . . 15 "
Mix, and add,
Vaseline . . . . . 85 " —M.

Apply twice daily.

In severe burns with fever, the author combated the fever by the internal administration of the following:

℞.—Boracic acid . . . . 4 parts.
Glycerine . . . . 10 "
Water . . . . 100 "
Syrup of poppies . . . 25 " —M.
Sig.—A teaspoonful every two hours.

4. In skin diseases, such as pemphigus, eczema, rhagades, rupia, and scabies, the results obtained with boracic acid have been most favorable. The formula used was:

℞.—Boracic acid (finely powdered) 10 parts.
Glycerine . . . . . 20 "
Lanolin . . . . . 30 " —M.

The treatment of scabies consists in first taking a warm bath and then rubbing the affected parts with boracic-vaseline salve (first, one to two; later, equal parts). The duration of this treatment averaged six days. In a case of granular conjunctivitis a cure was effected within forty-five days; a like result was obtained in some cases of pannus. Chronic scrofulous otitis is improved by lukewarm injections of concentrated boracic acid solutions; the application of boracic acid glycerine (one to ten) to stomatitis, aphthæ, or tonsillitis is followed by a curative effect.

5. For coryza:

℞.—Boracic acid (finely powd.) } equal parts.—M.
Powdered coffee }

Use as a snuff.

6. In some cases of chronic endometritis with leucorrhœa and sterility, the uterus was filled with powdered boracic acid, and then a boracic acid tampon applied. After removing the tampon, the cavity was irrigated with a boracic acid solution. A cure was generally effected after a three or four months' treatment, in some cases conception following.

7. In cystitis the bladder was washed out (in acute cases) with a three per cent. boracic acid solution, and in chronic cases this treatment was followed by the internal administration of from forty-five to ninety grains of boracic acid.—*Deutsche med. Wochenschrift*, January 24, 1889.

Eucalyptus Oil in Phthisis.—Dr. Philip, at a meeting of the Edinburgh Medico-Chirurgical Society, held January 16, 1889, stated that for eighteen months he has been administering pure eucalyptus oil internally in phthisis with great advantage. The preparation "compound eucalyptus cream" was the result of experiments carried out by Messrs. Baildon for the purpose of combining the drug with cod-liver oil. The emulsion contained 5 minims to 1 drachm of eucalyptus oil, and 75 per cent. of cod-liver oil. It was borne well by patients who could not take other preparations of cod-liver oil. The eucalyptus oil disguised the flavor of the cod-liver oil to a remarkable degree.—*British Medical Journal*, February 2, 1889.

Hydroxylamin in Skin Diseases.—Dr. Eichoff, of the Municipal Hospital, Elberfeld, has found an admirable substitute for pyrogallic acid, chrysarobin, and other powerful reducing agents used in external applications for skin diseases in hydroxylamin, which is, chemically speaking, an ammonia in which one of the atoms of H is replaced by HO. The most suitable compound for dermatological use is the chloride, the formula of which is $NH_2OH.Cl$. This occurs in colorless, strongly hygroscopic crystals, which are readily soluble in water, glycerine, or spirit, the solution showing an acid reaction. When introduced into the blood, hydroxylamin forms methæmoglobin, the blood rapidly becoming of a deep brown color. In large doses—that is to say, 0.01 gramme per kilogramme of body-weight—it produces hæmaturia in consequence of the destruction of the red corpuscles. It also acts on the nervous centres, producing narcosis. The high reducing power possessed by hydroxylamin renders it a powerful poison to low organic forms, and on this account it is to be very strongly recommended in dermatology.

The preparation used by Dr. Eichoff is the hydrochlorate dissolved in a mixture of equal parts of glycerine and spirits of wine in the proportion of 1 per 1000. This is applied with a brush to the affected parts of the skin, which must first be carefully washed with soap three to five times a day. In this way he has treated five cases of lupus, five of ringworm, and one of parasitic sycosis, with excellent results. These were specially remarkable in two cases of very severe lupus. Dr. Eichoff is hopeful that this remedy, which may sometimes, perhaps, be applied in the form of subcutaneous injections, may be found useful in psoriasis, parasitic eczema, and even in lepra and syphilis. He, however, warns those who propose to try it that it is a very powerful irritant, and that even for outward application a strength of 1 per 1000 is quite enough.—*Lancet*, February 9, 1889.

Treatment of Whooping-cough. — Dr. Genser (*La Clinique*), at a recent meeting of the Medical Society of Vienna, reported that he had treated some two hundred cases of whooping-cough, according to two methods. On some he practised Michaël's method of insufflations of medicated powders into the nasal passages, while to others he administered antipyrin by the mouth.

Michaël's method was tried in seventy-six cases; by means of a bent glass tube powdered benzoic acid was insufflated into the nasal passages. The results obtained were only fair; the duration of the treatment was forty-three days; and its only real advantage was that it put a stop to the vomiting. On the whole, it was not well borne by the little patients, whom it threw in a state of excitement and frequently produced severe attacks of coughing.

Antipyrin not only reduced the number of coughing fits, but also their severity and duration. In the majority of cases the duration of the treatment did not exceed twenty-four days. The average daily dose was one and a half grains for each year, so that a five year old child took, during forty-eight hours, fifteen grains of antipyrin in two and a half ounces of water flavored with some syrup. In five cases, complicated with pulmonary lesions, antipyrin gave negative results.

These facts seem to establish the favorable action of antipyrin in whooping-cough. The author asks whether antipyrin acts as an antiparasitic, or as a sedative, diminishing reflex excitability? He favors this last supposition, and concludes that although antipyrin is not a specific for whooping-cough, it renders valuable services in its treatment, being at the same time perfectly harmless in its action.

The author likewise tried antifebrin, but with results far less satisfactory.—*L'Abeille Médicale*, Jan. 28, 1889.

Treatment of Surgical Shock.—Dr. Christopher Heath, in an able paper on shock caused by surgical operations, recommends the following treatment: Half an hour be-

fore the operation to inject into the rectum with a long tube two ounces of brandy with four of hot water. This acts as a reserve of power which can be absorbed at leisure, and has the advantage over the administration of a stimulant by the mouth that it cannot embarrass the breathing. The injection can be repeated during the operation if necessary, and may be combined with the subcutaneous injection of ether. Lastly, the author strongly advises the subcutaneous injection of from gr. ¼ to gr. ½ of morphine, combined with gr. $\frac{1}{120}$ of atropine before the patient leaves the table, believing that not only is pain thus relieved, but that sickness is materially kept in check by the combination of drugs.—*British Medical Journal*, Feb. 2, 1889.

Cocaine for Difficult Dentition.—

℞.—Hydrochlorate of cocaine . 1½ grains.
Simple syrup . . . . ʒiiss.
Tincture of saffron . . . gtt. x.—M.

Apply to the gums several times daily.—*Deutsche med. Wochenschrift*, Jan. 31, 1889.

Non-parasitic Chyluria.—A somewhat anomalous case of hæmato-chyluria of a non-parasitic character is reported in *La Clinique* as having been in Prof. Desmeth's wards in the St. Jean Hospital, Brussels. The patient was a man of thirty, who attributed the commencement of his disorder to a chill. At first he suffered from pain in the epigastrium; this was followed by some tenesmus of the bladder, causing him to pass urine thirty or forty times a day, the urine being milky, and forming a solid clot on standing. This was the third attack of the same affection from which he had suffered. His general health was very fair. After admission it was found that the character of the urine passed was subject to considerable variations, being at times red, and forming a coagulum *en bloc*, at other times milky with little or no red tinge, and occasionally of a normal appearance. Sometimes these different types followed one another in regular order, but not always. Under the microscope the epithelial elements were found to be no more than normal; there were never any casts, and, what was more remarkable, never any white corpuscles, the opacity being due to the presence of red corpuscles and to that of fat in the form of exceedingly fine granules. Diet appeared to have no effect, and the "attacks of chyluria" seemed to bear no relation to meal-times.

Sigmund has reported a case in some respects similar to this, in which a fistulous communication existed between the lacteals and the bladder, but, as no white corpuscles were found in this case, there may not be any real analogy between the two, though they agreed in an entire absence of filaria sanguinis or any other parasite. The only drug which appeared to exert even a slight effect was copaiba.—*Lancet*, February 9, 1889.

Statistics of Operations on the Gall-bladder.—DR. A. DEPOGE (*Journ. de Méd. Brux.*, 1888, No. 24) states in a thesis entitled "Surgical Intervention in Gall-stones," that up to date 78 cholecystotomies have been performed. Of these, 6 were after the method of Spencer Wells, and in the remaining 72 the bladder was sewed to the abdominal wall. Of the first series, 3 died of acute peritonitis, 1 case which had been cured had a relapse, and 2 were completely cured. Of the second series, 11 died; of these, 5 from hemorrhage and collapse, 2 of biliary engorgement, 2 of overflowing of the bile into the peritoneum, and 2 of undecided causes; besides these, 4 died in consequence of secondary complications.

Among the cures obtained were 24 cases of fistula of the gall-bladder, some of which were permanently relieved.

The number of cholecystectomies was 22, with 2 deaths from occlusion of the bile-duct, and 1 death, after a perfect cure had been established, from a cause independent of the original trouble.

Thus the death-rate from cholecystotomy in which the gall-bladder was sewed up and returned to the abdominal cavity, was 5 per cent., while in cholecystotomy in which the bladder was sewed to the abdominal wall it was 15.27 per cent., and in cholecystectomy it was 9.99 per cent. As this last number includes the 2 cases of permanent occlusion of the gall-duct, the results of these statistics would show (if these 2 cases are omitted) that cholecystectomy, as compared with cholecystotomy, deserves to hold a better position in our estimation than it has heretofore.—*Deutsche med. Wochenschrift*, Jan. 31, 1889.

Treatment of Acne.—DR. HERMANN ISAAC, of Berlin, recommends the following for the treatment of acne:

℞.—Naphthol . . . . 10 parts.
Precipitated sulphur . . 50 "
Green soap, Vaseline } . . . āā 20 " —M.

This ointment is applied by means of a hard brush, and allowed to remain from one-half to one hour, according to the intensity of the eruption. Desquamation, and with this some irritation of the affected parts will be observed the following day. The applications are renewed daily, until the desquamation is complete. Should the irritation be too severe, it is well to intermit the treatment for a few days, and apply a two per cent. salicylic ointment.

For very obstinate cases, Dr. Oestreicher recommends the following:

℞.—Powdered chalk . . . 5 parts.
Naphthol, Camphor, Vaseline } . . . āā 10 "
Green soap . . . . 15 "
Precipitated sulphur . . . 50 " —M.

The addition of camphor increases the desquamative action of the ointment, which, in order to avoid all irritation, should not be left on longer than fifteen minutes.

Another remedy which has proven efficacious is resorcin:

℞.—Resorcin, Oxide of zinc, Starch } . . āā 5 parts.
Vaseline . . . . . 10 " —M.

Dr. Isaacs has tried this remedy in numerous cases, with the best results. Under no circumstances should the ointment contain more than twenty per cent. of resorcin, as in larger doses it becomes an irritant. Medicated soaps greatly assist the action of these remedies, and should, therefore, not be discarded.—*Berliner klin. Wochenschrift*, Jan. 21, 1889.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, MARCH 2, 1889.

THE DIMINUTION OF INFANT MORTALITY.

IN no period of life is mortality so great as in infancy. It has been commonly held that this was unavoidable, but a closer study of disease in infants, and of the many infective agents which attack them directly, or indirectly through the medium of food, has modified this belief, and there has been gradually brought about a diminution in the death-rate of infancy.

In manufacturing centres a recent estimate in the *Lancet* fixes this mortality at 200 in every 1000 infants. That this is dependent, not on ignorance and carelessness alone, but on cupidity also, is shown by the fact that from 28 to 60 per cent. of these children had been insured in companies paying from $25 to $35 in the event of death. Another evidence of the possibility of preventing infant mortality is found in the mortuary report of Liverpool for five years, which estimates that in this time 700 children were suffocated by parental carelessness, often the result of intoxication. Of 50 cases of sudden death in infants 22 per cent. occurred on Sunday morning, caused by Saturday night's debauch. In seeking to remedy these evils, the physician can coöperate with the authorities by closely scrutinizing the circumstances under which he is asked to give a death certificate, and by promptly reporting to the proper organization cases in which the lives of infants are jeopardized by ignorance and vice.

His further duty in securing proper hygiene for infants is outlined by Wyss in a recent number of the *Correspondenz-Blatt für Schweizer Aertze*. Physicians should prevent, if possible, the overcrowding of dwellings and the diminution of proper air space. Children who are boarding, whether with individuals or in asylums and institutions, should be under the observation of physicians, who should instruct those who care for the inmates and regulate their condition. It is the duty of practitioners to insist, whenever possible, that the mother nurse her child, and to discourage all foods and beverages except milk. Midwives and nurses must be properly educated in caring for infants before they are allowed to graduate and practise. Births must be promptly reported, and the city authorities should furnish each mother brief directions for caring for her offspring: this information should also be given to asylums and disseminated as widely as possible.

Indigent mothers who are capable should be given opportunities to act as wet-nurses, and midwives should encourage such mothers in this. The attention of the authorities should be directed to fraudulent and injurious infant foods offered for sale. A most important question is the care of the milk supply of a city. This is best performed by a bureau of milk inspection, whose officials should secure the selling of pure milk only.

The authorities of asylums, maternities, and hospitals have an especial duty in preventing the early separation of mother and child, and in encouraging the maintenance of suckling as long as possible. The legal requirements of an adoption should be strictly enforced, and the infant life be jealously guarded. Infant insurance is not unknown in America, and there are many avenues of escape from the responsibility of infantile life open to the careless and vicious; the physician should join hands with the authorities in dissipating ignorance and preventing crime.

ANTHRAROBIN.

ANTHRAROBIN, which was originally discovered by Liebermann, seems to possess equal value with its relative chrysarobin and to be capable of substitution for this substance in the treatment of skin disease. It is a yellowish powder, tolerably stable in a dry atmosphere and is not soluble in acids or water, but readily soluble in dilute alkaline solutions or alcohol, at first making a solution of a brown

color, which as oxygen is taken up passes to a green and finally a violet.

Therapeutically, anthrarobin has been employed by ROSENTHAL and by BEHREND, and more recently KÖBNER has recorded in the *Wiener medicinische Presse*, No. 53, 1888, his experience with it, employing it with good results in a 10 to 20 per cent. solution in the various forms of tonsurans as a wash. Rosenthal has used it in psoriasis and pityriasis versicolor and herpes, and Behrend asserts that it is often better in its effects upon the skin than chrysarobin, as it produces less inflammation and only discolors the skin slightly. It also possesses the additional value of making so slight a stain on the linen that it can be removed by washing.

According to most authorities, it is best to keep it in alcoholic solution and if the bottle is well corked such a mixture remains good for a week.

SULPHUROUS ACID GAS AS A DISINFECTANT.

DR. E. R. SQUIBB, in his address as President of the King's County Medical Association, at Brooklyn, N. Y., deals with the important question of sulphur-fumigation in the prevention of infectious disease. He holds that there should always be a free and abundant presence or liberation of aqueous vapor in the apartment in which the sulphur is burned, and points out the fact that very little emphasis is given to this essential particular in the printed instructions issued by boards of health. It is true that these instructions sometimes recommend that the vessel in which the sulphur is to be burned shall be placed within another larger one containing water, but this course has been advised more on the score of security against fire than as an essential advantage in the generation of the sulphurous acid gas; the heat developed by the burning sulphur effects the vaporization of a certain amount of water, which is useful. In the report of a certain State Board of Health, now before us, the recommendation is made to "suspend the vessel over a tub of water," a course not at all promotive of the fumigating process. In the absence of moisture the penetrating power of sulphurous acid gas is very slight, while it is of the highest importance that the agent shall come into intimate contact with the germs that are to be destroyed by it.

In view of the fact that tons of sulphur are burned annually, under the directions of sanitary officials, in an atmosphere practically dry, the pertinence of these views becomes apparent, and it will be necessary for some of our health officers to revise their circulars of information, in order to reach a higher degree of efficiency in this branch of their preventive labors. In this view it will be advisable for them to go beyond the recommendation to burn sulphur in a pot that is in contact with water, and to provide for the moistening of the walls and carpets and other porous fabrics, by sprinkling water over them in advance of the ignition of the sulphur, and to have water boiling in the apartment while the process is under way. In this connection, however, the bleaching properties of the gas should not be overlooked.

Dr. Squibb also called attention to the relative inertness of chlorine gas as a disinfectant in the absence of aqueous vapor. These forms of gaseous disinfection have obtained so great currency and confidence that it is highly desirable to make them as efficient as possible; our sanitarians will be among the first to appreciate the force of these suggestions.

The Maryland Medical Journal announces, by authority, that the Trustees of Johns Hopkins Hospital have appointed Dr. William S. Halstead, of Baltimore, Surgeon-in-Chief to the Dispensary, and Acting Surgeon to the Hospital. By their authority, Dr. Halstead will at once go to Europe to purchase such surgical instruments and medical appliances as may be required for the Hospital, a liberal appropriation having been made for this purpose. The ceremonious opening of the Hospital will take place on Tuesday, May 7, 1889, and patients will be received a few days later.

IT is announced that the University of Pennsylvania will erect, at an early day, dormitories for the use of its students, and a large proportion of the medical students have already signified their intention of availing themselves of the facilities which will be thus afforded.

UNDER the will of Mr. J. Ingersoll Bowditch, of Boston, Harvard College will receive $6000, the income from which is be expended under the direction of the Professor of Physiology, for the promotion of original investigations in the Physiological Laboratory of the Harvard Medical School.

DR. B. ALEXANDER RANDALL has been elected Professor of Diseases of the Ear, and Dr. Edward P. Davis has been chosen Professor of Obstetrics

and Diseases of Children in the Philadelphia Polyclinic and College for Graduates in Medicine.

At the meeting of the Clinical Society of London, on February 1st, Dr. S. Weir Mitchell, Sir William Jenner, Sir Joseph Lister, Prof. W. T. Gairdner, and Prof. von Nussbaum were elected Honorary Fellows of the Society.

A German edition of Dr. St. John Roosa's *Treatise on the Ear* has just been published in Berlin.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 21, 1889.

The President, Alfred L. Loomis, M.D., in the Chair.

Dr. Charles McBurney read a paper on

THE TREATMENT OF INGUINAL HERNIA WITH REFERENCE TO RADICAL CURE.

He said that, in view of the fact that so much had been written of late in regard to the radical cure of hernia, he hesitated to express his views on the subject, but at the same time the present contribution was the result of much thought and labor. Before giving the details of the operation which he advocated, he thought it well to present something of the line of thought which had induced him to adopt it. In 1886 he met with two cases in which a return of the trouble after operations for the radical cure of hernia convinced him that one great essential to success in any such procedure was the complete removal of the sac. The first predisposing cause of hernia was the pouching of the peritoneum at the internal ring, and in order to cure a hernia it was necessary first to prevent laxity at this point, and then to support the peritoneum firmly at this point.

These points were now recognized by all surgeons, and, consequently, the older methods of operating for a radical cure had been abandoned. He then referred to various methods designed to eradicate the sac completely, and gave a more particular description of Macewen's operation. In this procedure a stitch is firmly taken at the distal extremity, and the end of the suture is then passed in a proximal direction, several times through the sac, so that when pulled upon the sac becomes folded on itself, like a curtain. The free end of this stitch, threaded in a hernia needle, is made to traverse the canal, and to penetrate the anterior abdominal wall about an inch above the anterior ring, the wound in the skin being pulled upward, so as to allow the point of the needle to project through the abdominal muscle without penetrating the skin. The thread is pulled through the abdominal wall, and when traction is made upon it the sac, wrinkling upon itself, is thrown into a series of folds, its distal extremity being drawn farthest backward and upward. An assistant maintains traction upon the stitch until the introduction of the sutures into the inguinal canal, and when this is completed the end of the stitch is secured by introducing its free extremity several times through the superficial layers of the external oblique muscle. A pad of peritoneum is thus placed upon the abdominal side of the external opening. To accommodate this wrinkled-up pad the parietal peritoneum is previously stripped up for half an inch around the whole abdominal aspect of the circumference of the external ring.

This method, Dr. McBurney said, when practicable, undoubtedly removed the sac; but it was often difficult or impossible to carry out, and he referred to some of the classes of cases in which it was impracticable. In selected cases, however, remakable results had been obtained with it. He next spoke of Ball's method of twisting the sac until its tubular character was entirely destroyed, which, he said, was a somewhat blind method and not free from serious objections. Some sacs also were altogether untwistable. In his own operation the anterior wall of the canal was split all the way up to the internal ring. This procedure he had supposed was original with himself, but he afterward learned that it had been previously practised by Riessel. This exposed the whole length of the sac, and when this was done there were two methods of disposing of the neck of the sac, viz., by ligature and by suture; either one of which might be adopted according to circumstances. In this way it was very easy to restore the natural smoothness to the peritoneum, which he regarded as so essential to success. In all cases where it was applicable he much preferred the ligature to the suture.

The only certain method of closing the entire canal, except that portion of it occupied by the cord, was the open treatment of the wound, and even this was very difficult in many respects. It was necessary that the whole wound should be packed very closely in order to secure granulation throughout its entire length. The objection had been raised against cicatricial tissue that it melts away and in time yields. It was a fact, however, that the strength of cicatricial tissue was often a powerful instrument both of benefit and injury; and in this connection he referred to the cicatrices of burns. He had also heard it argued that cicatricial tissue does not prevent the frequent occurrence of ventral hernia after laparotomy; but the circumstances here were very different, since the transversalis fascia after the operation for hernia lay, for the most part, intact behind the peritoneum.

Some operators had practised the method of sewing up or narrowing the internal ring; but in reality, since the ring was naturally open quite wide, the stitches were of no avail in narrowing it. As a rule, there was a considerable quantity of loose connective tissue in the ring.

Dr. McBurney then proceeded to give the details of the operation employed by him for the past two years. Careful antiseptic precautions having been taken, a free incision is made, beginning a little outside the intestinal ring, and this is rapidly deepened over the whole length of the canal. Having cut through the external spermatic fascia and dissected down to the canal, the anterior wall of the latter is split up to the outer edge of the internal ring. The deeper layers of the sac are dissected off and the cord is separated from the sac up to a point a little within the abdomen. The whole sac is lifted up, so as to expose it completely up to its neck, and adhesions are separated, and, if necessary, a portion of omentum

cut away. The sac is then held high up from the internal ring, so as to prevent the return of any portion of intestine or omentum, and a ligature is applied at the very highest point. In congenital hernia, however, it is often necessary to suture, instead of ligating.

The wound is left entirely open, and from four to eight stitches are used to fix together the skin and the tissues which form the upper wall. As many more are employed for the lower wall; but as the wound is unnecessarily wide, additional tension sutures are passed deeply through the skin and superficial fascia. Iodoform is freely dusted about the wound, and then the latter is closely packed with iodoform gauze; it being one of the essentials to success that the packing should be thoroughly done. The scrotal or labial end of the wound is sewed up without packing, and a drainage-tube inserted at its lower extremity. Great care must be used in making the external dressings, and in order to prevent any contamination by urine, rubber bandaging is employed in the case of adults, and a plaster-of-Paris casing in children. Frequently the urine is also drawn with a catheter for several days succeeding the operation. Five or six weeks, at least, are required for the healing, but Dr. McBurney believes that this comparatively long period in the prone position is time well spent in such cases. None of his patients is allowed to wear a truss or support of any kind after the operation, as he regards such appliances as positively injurious under the circumstances.

The advantages which he claimed for the operation described were the following:

1. It is the only method in which the sac is completely obliterated.

2. The walls are very firmly united throughout their length.

3. The wound being open, septic complications are avoided.

4. The rapidity with which the operation can be performed renders it applicable in a great variety of cases.

He said he had now employed this method in thirty-six cases. There was one fatal case, but this result was due to alcoholism. In three the wound became infected, and the healing was slow; although there was no general sepsis in any of them. In one case orchitis was set up, and in one there was a relapse of the tumor; the cause of this relapse being undoubtedly the fact that the sac was not ligated sufficiently high up. Dr. McBurney said, in conclusion, that he had either personally seen or had heard from thirty-one of the cases within the past week, and that the result in all was thus far perfect. Of the remaining cases, two could not be found and two were still under treatment. He presented a considerable number of his patients for examination, and said that in order thoroughly to test the case he considered it necessary to invert the scrotum on the finger.

DR. L. A. STIMSON said that he had come to the meeting prepared to express his conviction of the value of Dr. McBurney's method, and he now wished also to express his appreciation of the admirable manner in which the matter had been set forth in the paper. So far as regarded the first step of the operation, the ligation of the neck of the sac and the restoration of the peritoneum to its normal state, he had nothing to add to what had been already said. As to the use of the cicatricial packing, he thought Dr. McBurney was deserving of great praise for coming out squarely against the old idea that cicatricial tissue is not strong. He wished to call especial attention to one of the chief advantages of the method, upon which Dr. McBurney had not dwelt, and that was, the very great freedom from the risk of septic processes which characterized it. There was no necessity for drainage, and no drainage was employed except at the lower end of the wound in the scrotum, the wound above being left entirely open.

To realize the full advantages of the operation it was necessary to consider the alternative measures that were at our disposal. He said he had to confess that when Dr. McBurney first proposed it, he was not favorably impressed, as he did not like the idea of keeping a patient in bed for six or seven weeks. He therefore endeavored to shorten the time by inserting a drainage tube within the canal, with the idea of limiting the suppuration to a portion of the wound; but he found that the patients were even longer in getting well than in Dr. McBurney's cases, and therefore abandoned the modification. The alternative measures of treating the canal were all comprised in an attempt to restore the original canal. In many old hernias there was, in fact, no longer any canal. The internal ring was dragged down until it overlapped the external, and there remained simply a hole covered by the peritoneum to one side, and by the skin and subcutaneous fascia on the other. There was a complete absence of the valvular arrangement of the sides met with in the normal canal. Many surgeons had attempted to restore this valve-like arrangement, and always failed. Now, if we could not restore the canal some alternative for this must be sought; and this formation of a plug of cicatricial tissue for supporting the peritoneum seemed to be a very satisfactory device. The only fear that he had had in regard to the method was that a hernia might possibly be produced at the margin of the cicatrix. In the case in which there was a relapse he should like to inquire of Dr. McBurney how the new hernia occurred.

DR. A. P. GERSTER said that, as regards the question of radical cure, the whole matter was still in an experimental stage. Time must furnish the only test, and the measures which were now employed for the accomplishment of this purpose were of such recent origin that we cannot as yet arrive at a decision. A large number of cases were also required in order to form a positive opinion. In regard to the exposure and treatment of the sac, all were agreed that it was important to reach up as high on the neck as possible, and Riessel's step of slitting up the anterior wall was no doubt a great advance. Operations of this character were necessarily complicated, and no two cases were exactly alike. In many old hernias he did not consider it necessary to slit up the anterior wall of the canal, as the upper part of the sac could be reached sufficiently well without this. There was one objection to the method which had not been mentioned. While the condition after the operation was not analogous to that after laparotomy, where ventral hernia was very liable to occur in cases where a drainage tube had been inserted into the peritoneum, there was another class of cases in gynecological practice in which the analogy was very close. He referred to those cases in which intra-mural abscesses occurred, which furnished frequent examples of the formation of ventral hernia. Here, as in cases of hernia treated by Dr. McBurney's

method there were a smooth peritoneum and a broad wound healed by cicatricial tissue.

Dr. Robert Abbe said it was perfectly true that we were obliged to leave the question of radical cure to time, but he still thought it was desirable that an expression of opinion in regard to various methods should be elicited. During the past year he had performed Dr. McBurney's operation in 17 cases, and he felt entirely convinced that it was the best that we now had at our service. In all, he had operated in 117 cases, and 52 of these were by Macewen's method, by which he had been much attracted. Macewen claimed that other operators did not succeed as well as he himself with it, because they did not operate in the right way; but if the procedure was so difficult that only Macewen could perform it properly it was scarcely worthy of the confidence of the profession. He had also employed Mitchell Banks' and other methods; but had now abandoned them all for McBurney's. One of the great advantages of the latter was the simplicity of the operation in general practice. He had not yet felt willing to leave his patients without a truss after the operation.

Dr. A. J. McCosh said that it seemed to him that enough time had elapsed to convince surgeons of the advantages of the McBurney method, and the great popularity which it had attained was a strong argument in its favor. During the past fifteen months he had had four cases, and they were all perfectly satisfactory. Like Dr. McBurney, he entirely abandoned the use of a truss after the operation.

Dr. Frank Hartley had tried various methods, and found none of them so successful as Dr. McBurney's. He believed that the cicatricial tissue was sufficiently strong for the duty required of it, and that the destruction of the funnel-shaped process of peritoneum leading to the sac tended to prevent pressure upon the cicatrix.

Dr. F. W. Murray presented a patient on whom he had operated by McBurney's method, with very good results, for double scrotal hernia of over twenty years' standing.

Dr. V. P. Gibney had seen some relapses after Dr. McBurney's operation (performed by other surgeons), but whether the method had been strictly followed according to Dr. McBurney's directions or not he was unable to say. It was a fact, however, that the relapses were fewer than after any others. He used to think that in the case of the return of a hernia after operation a truss could be more easily worn than before; but he did not think so now, as in some instances there was great difficulty in managing the truss, and it was necessary to repeat the operation. It was a very satisfactory point that the risk of the operation had been reduced to a minimum, and this, of course, was a great advance. He did not feel so confident about the utility of cicatricial tissue as some of those who had spoken, and after Willis's operation for shortening the tendo Achillis he had found that after four or five years the cicatricial tissue had stretched.

Dr. McBurney, in concluding the discussion, said that as to the manner of the recurrence of the hernia in the one case that relapsed, it was precisely the same as that seen in inguinal hernia under ordinary circumstances. Pushing the cicatrix aside the descending hernia followed the course of the cords to the external ring. The cause of the relapse he had already explained in the paper. In regard to the test of time, no results could, of course, be claimed if it were said arbitrarily that we must wait ten years before deciding as to the validity of the cure in any given case. While, however, longer time was certainly to be desired, he thought we could at least study the principles of the operation. He had not, with a single exception, refused to operate in any case. The exception was an old man with advanced Bright's disease and in a generally broken-down condition. Some of the cases were of congenital hernia. In every case except the one in which the relapse occurred he was satisfied that the sac was completely obliterated and the peritoneum rendered smooth. As to omitting to split the canal in certain old cases where the ring might perhaps be two inches in diameter, as suggested by Dr. Gerster, he claimed that even in this class of cases the sac could not be obliterated unless the canal was slit up so that the ligature could be applied at the highest possible point. He thought there was a misconception of the object of the cicatricial tissue in the minds of some, and it was not analogous to that mentioned by Dr. Gibney in referring to the shortening of the tendo Achillis. Thus the cicatrix was subjected to continuous pressure, but after his operation there was never any direct intra-abdominal pressure upon the cicatrix; the pressure being made first upon the peritoneum. Just as a very small amount of pressure would often keep a hernia which had not been operated on in place, so a slight pressure was all that was experienced after the operation. Although he hoped for the contrary, it might be that some of his cases would relapse in the course of time. So far, however, with the exception of the instance mentioned, he had failed to find any evidence of threatened or commencing recurrence in any of them.

Section on Theory and Practice of Medicine.

R. C. M. Page, M.D., Chairman.

Stated Meeting, February 19, 1889.

Dr. S. Seabury Jones read a paper on

SIMPLE, NON-TUBERCULAR, NON-METASTATIC ABSCESS OF THE LUNGS.

This is a subject, he said, which has received but little attention. Simple abscess of the lungs is, however, comparatively rare; and it would, doubtless, occur more often than it does, were it not, as Stokes has pointed out, that the lungs are provided with such an admirable natural system of drainage through the bronchial tubes. Practically speaking, it is liable to be met with in one of four forms. The first is that in which the symptoms are very obscure from the beginning, and remain so until there suddenly occurs a discharge of purulent matter. In the second form, the symptoms resemble those of pleurisy with effusion; and, in the third, those of pulmonary tuberculosis. The fourth is that associated with the variety of pneumonia, which advances slowly from one lobule to another, or is characterized by a tendency to skip from one lung to the other.

Dr. Jones said he had personally met with all the forms except the first; but undoubted cases of this variety, occurring in the experience of others, are on record. Abscess of the lungs is always accompanied with a de-

preciation of the general health, and alcoholism is apparently a prominent factor in its production. It is an affection confined to no particular age, and Dr. L. Emmett Holt, of New York, has reported in the *Medical Record* a case that occurred in an infant only three months old. When he encountered his first case, now nine years ago, he was unable to find any reference to the subject whatever in any of the text-books. This case he proceeded to narrate. The patient was a man seventeen years of age, of rather delicate general health, and affected with slight lateral curvature of the spine, and he first came under observation September 25, 1879. He was in his usual health when he was attacked with severe pain in the left side, accompanied with cough, but no expectoration. At the time he was seen the pulse was 120, and the temperature 102°. Anteriorly there were no abnormal physical signs, but posteriorly, in the subclavicular region on the left side there was complete dulness on percussisn, although no râles whatever could be found. There was still no expectoration. About October 1st a large abscess of the tonsil developed, from which pus discharged freely, and subsequently there was a discharge of purulent matter from the lungs through the mouth. After this the patient made a rapid recovery, and had no further trouble afterward.

He was led to consider this as a case of simple abscess of the lungs: *first*, on account of the short time intervening between the first symptoms and the discharge of pus; *secondly*, on account of the occurrence of the tonsillar abscess, showing a tendency to the formation of abscesses in the system; *thirdly*, from the rapidity of the recovery; and, *fourthly*, because of the dulness found on physical exploration being exclusively posterior. He was afterward confirmed in his opinion in regard to the nature of the case by the report of a case published by Dr. Henry Payne, in the *Lancet*, in 1882. The patient was a male, twenty-three years of age, who was admitted to the Ashton-under-Lyne Infirmary in June, 1881, with well-marked signs of pleuritic effusion on the left side; the trouble having commenced in the previous February with chills, pain in the side, and feverishness, the result of getting wet through. He was treated for pleurisy at this time, and recovered sufficiently to attend to his work until April, when he experienced difficulty in breathing, shortness of breath, and slight cough. He spat blood once or twice, and continued to grow worse until his admission to the hospital in June. He was treated, without improvement, until August 20th, when the following condition was noted: The patient has lost flesh since admission. The left side bulges more than the right, and measures one inch more round; movements on this side are deficient; there is absolute dulness on percussion, both back and front; no breath-sounds are heard, and the vocal fremitus and resonance are absent. The breathing on the right side is exaggerated. He has a slight cough, but no expectoration of any importance. Has night-sweats. The temperature every evening has been above 100°, and the pulse invariably above 100.

From these symptoms an empyema was suspected, and an exploratory puncture discovered pus. Accordingly, upon August 23d, an incision about two inches long was made just above and parallel to the seventh rib in the anterior axillary line, antiseptically and under chloroform. Upon opening the pleura there was a very profuse hemorrhage of dark venous blood, which could only be arrested by the injection of perchloride of iron solution. About fifteen ounces of pus escaped, and a drainage tube was inserted. There was a very profuse discharge, which in a few days became fetid. The patient continued to do fairly well until the 29th, when the temperature suddenly rose to 104°, and, after suffering severe pains in the chest, he died on the 30th. The autopsy showed the whole of both surfaces of the left pleura adherent, without a drop of fluid in the sac. The external opening made in the chest-wall led into a large, irregular cavity situated in the centre of the lung, which was in a state of gray hepatization. Dr. Payne regarded it as undoubtedly a case of pneumonia, terminating in the formation of an abscess.

Dr. Jones's second case was observed in 1886. The patient was a male, forty years of age, who was attacked with tonsillitis. There was suppuration accompanied with pain, which was ushered in by a chill, and on an incision being made in the tonsil there was a considerable discharge of pus. Subsequently he had another severe rigor, followed by high temperature, and coughed up a cupful of pus and dark blood. Still later there was another of similar character. In this case there was an area of dulness at the base of the right lung, with local tenderness on pressure. The matter coughed up was found on microscopic examination to contain the pneumococcus of Friedländer.

The third case was one in which the symptoms resembled those of tuberculosis. The patient was first troubled with palpitation of the heart, which he believed to be due to gastric derangement. There was a considerable loss of flesh, (amounting to forty pounds), and the temperature ranged from 100° to 102°. Physical examination revealed an area of dulness in the right sub-clavicular region. Dr. Jones prescribed quinine and a general tonic treatment, and sent him to the country for the summer. In July he coughed up a considerable quantity of pus and dark-colored blood. Afterward the expectoration was profuse, and he suffered from night-sweats and became greatly emaciated. He then began to improve, and as repeated examinations of the sputa failed to detect at any time the presence of the bacillus tuberculosis, the case was regarded as one of simple abscess of the lungs, and a favorable prognosis made. In a few weeks the patient regained his usual health and weight; although a small cavity still remained in the lung. Two years afterward he was seen, in excellent health, and no sign of a cavity could be detected.

He next narrated a case reported in the *Lancet* in 1884 by Mr. T. Pridgin Teale. The patient was a male, fifty-four years of age, who had been ill for three months, and the earlier history of the case was very obscure; commencing with a cold, shivering, loss of flesh, vomiting and retching, and pain in the hepatic region, but without cough or any symptom of lung disease. About two weeks before he was seen by Mr. Teale, Dr. Clifford Allbutt found the hepatic dulness increasing upward, as if there were fluid in the lower part of the thorax, and a week later Dr. Myrtle saw the patient, and, finding dulness occupying the lower half of the right lung, came to the conclusion that fluid was present, and advised early tapping. The right side of the thorax was accordingly punctured low down with the small trocar of Bartlett's aspirator, but only two drachms of fluid, clear and straw-colored, could be ob-

tained with the suction of the aspirator. Being still confident that fluid was present, Mr. Teale made a fresh puncture higher up, when very offensive, thin greenish pus appeared; and after careful and continuous aspirations about a pint of pus was slowly withdrawn. In consequence of the unexpected character of the case two hours later a consultation was held, and it was decided that as soon as the temporary relief afforded by the tapping had passed away the thorax should be opened and drained. By a fortnight afterward the patient had became more hectic, had expectorated for two days most offensive pus, and was altogether extremely ill. On the right side there was continuous dulness extending upward in front to about the level of the fifth rib, a little below the nipple, and laterally round the axilla, and diminishing toward the spine. In the recumbent posture a spot could be made out in the front of the chest having a peculiar "cracked-pot" resonance in the middle of a dull area. No râles. An incision was made at the site of the puncture, and the pleura opened. No pus appeared, only a small quantity of serum. The lung felt dense and boggy, instead of crepitant and elastic. On reintroducing the trocar and puncturing the lung, pus appeared. The puncture was enlarged so as to admit the finger, and two pints of exceedingly fetid pus escaped. A drainage-tube was inserted, and the cavity syringed out with a weak solution of carbolic acid. The after-progress of the case was extremely critical and tedious, but the patient finally made a good recovery.

Trousseau stated that for his first twenty-five years of hospital practice he had never met with a case of simple abscess of the lungs. Afterward he found two cases. Leannec met with only five cases in several hundred autopsies in those who had died of pneumonia. "Moreover," he wrote, "they were inconsiderable, few in number, and scattered through the lungs, which presented the third degree of inflammation." In 1848, Robert Graves reported six cases.

Simple abscess of the lung was no doubt more frequent, however, than was generally supposed, and in the future it would be more easy to recognize than formerly, since Koch's brilliant discovery of the bacillus tuberculosis now enabled us to make a differential diagnosis. In Pepper's *System of Medicine* some attention was given to the affection, and it was defined as a circumscribed suppuration of the lung resulting in a cavity. In von Ziemssen it was referred to only as a sequel of croupous pneumonia. In 1885, Dr. Andrew Dunlap described an interesting case in the *Lancet*, in a man fifty-three years of age, of intemperate habits. Dulness on percussion with weak breathing was discovered below the right nipple. This gradually extended upward until, in about a week, there was dulness, with almost inaudible respiration, up to the second rib. Posteriorly, there was dulness about two inches upward from the base, with weak rough respiration. Shortly afterward a prominence of considerable extent was noticed in the mammary region. This tumor seemed to originate beneath the ribs, which were bulged outward by it, and it was hard to the touch. The tumor was aspirated, and about ten ounces of pus withdrawn, which was followed by some subsidence of the tumor. At the end of a month the upper part of the tumor was less prominent, while, at least, the upper half of it was tympanitic on percussion. During this time the patient had been spitting up an ounce or two of curdy pus daily, and during the last ten days it had also been escaping from the puncture made by the aspirator needle to the extent of one or two ounces in the twenty-four hours. He gradually failed, and died about two and a half months later.

Lassen, of Kiel, had reported six cases, Runeberg, of Sweden, had collected eight (including one of his own), all of which were operated on, and, including the three cases narrated in the present paper, there were now on record thirty well-authenticated cases, exclusive of Graves's six cases, all of which recovered. Of the thirty, sixteen were operated on, and fourteen were not operated on. Of the former, four died, and of the latter, two. The main point, when an abscess had manifested itself, was to decide between tubercular and simple abscess. The rapidity of the development of the symptoms was always in favor of simple abscess, but the real test was to be found in the microscope. If in any case an operation was decided upon, free incision was no doubt the best procedure. Dr. Jones said that he had not been favorably impressed with the results obtained from the injection of tuberculous cavities. He would only operate, however, when the indications for operation were perfectly clear.

The Chairman said that the paper was quite a revelation to him. He had personally never met with a case of pneumonia terminating in abscess, and Wilson Fox and other authorities had stated that abscess of the lungs was very rare. Nothing had been said in the paper in reference to pulmonary abscess resulting from the presence of foreign bodies. He had seen a case in which an abscess developed on account of the presence of a bullet which had entered the lung tissue twenty years before, the patient having been wounded in one of the battles during the late war. He was thought to have a cavity, and was troubled with cough and hemorrhage. The case resulted fatally, and at the autopsy an abscess with the bullet in it was found. Reynolds related a similar case in an old Waterloo soldier, where the bullet remained in the lung forty years before the abscess developed.

Dr. A. L. Loomis said that the paper, with its three original cases, and its records of other cases, constituted a valuable contribution to the somewhat meagre literature of this subject. In his own experience simple abscess of the lung was very rare. He had, however, seen a very few cases which were regarded, and very properly he thought, of this nature, and in one or two instances the diagnosis was proved by post-mortem examination. In all cases, so far as his knowledge went, in which abscess had been observed, it had been preceded by the signs of inflammation more or less active, and it occurred in those in a condition favoring the development of abscess. He believed that such abscesses formed in lungs which were previously the seat of fibrinous pneumonia followed by an increase of connective tissue. When subjected to a not very active chronic inflammation abscesses were liable to form in this tissue. Such abscesses also occurred altogether in alcoholic subjects, and he had never seen them in any other. There was one point which Dr. Jones had touched upon to which he desired to call attention. It was, in his opinion, very difficult to draw the line between circumscribed empyema in certain positions and abscess of the lung, and especially if such empyema broke into the bronchial tubes, so as to allow of the escape of pus. He

thought that he may have made such a mistake himself. In any case of his own he should be very loath to pass a knife into the lung tissue, and he fancied that the necessity for such a procedure was very rare. As a rule, it diminished the chances of the patient's recovery, and it was better to leave the abscess to open spontaneously. We are certainly indebted to Dr. Jones for directing attention to this subject, and urging greater care in the matter of diagnosis.

DR. JONES in closing the discussion said that in two of his cases he had the opportunity of examining the sputa, and as there was in both instances an entire absence of the tubercle bacillus, it was on this circumstance that he based his opinion of this non-tuberculous character.

DR. A. L. STERN exhibited

WEIGERT'S HOT-AIR INHALATION APPARATUS FOR THE TREATMENT OF PULMONARY TUBERCULOSIS.

This consists of two cylinders of copper, one within the other; the air to be inhaled is heated to a minimum temperature of 212° F. by means of a Bunsen burner, and thus rendered perfectly aseptic, passes up between the two. The inhalation is to be used for four hours each day, two hours at a time, and it can be taken either in a sitting or reclining posture. It is advised, however, that when first commencing the treatment, the patient should use the apparatus for only thirty minutes twice a day.

The temperature of the air inhaled is gradually increased from 212° to as high a point as the patient can bear without suffering inconvenience; 482° being the highest temperature yet reached in any case in these inhalations. Dr. Weigert, the inventor of the apparatus, is a graduate of the College of Physicians and Surgeons of New York, but is now residing in Berlin.

As a result of the hot-air inhalation, Dr. Stern said, "there is an acceleration of the pulse, while there is a diminution in the frequency of the respirations, and the inspirations become deeper. There is at first an elevation of the temperature, the rise being from one to two degrees; but after about an hour the temperature again subsides. The difficulty of breathing incident to consumption is soon markedly relieved, and there is at first a lessening and then a total cessation of cough. Under the use of the inhalations there is at first an increase, then a decrease, and finally total disappearance of expectoration. All catarrhal symptoms disappear, and also the fever and night-sweats. There is a clearing up of the infiltrated portions of the lung, and cicatrization of cavities, when these exist, is brought about; while the strength, weight, and appetite of the patient gradually increase. The microscopic examination of the sputa generally shows at first an increase in the number of tubercle bacilli; but afterward there is a total disappearance of the bacilli, and a complete cure of the case is effected. The shortest period in which total disappearance of the bacilli has been noted is four months. This method of treatment, he said in conclusion, has now been employed in one hundred and fifty cases, fifty of which were published in Vienna, and the Chairman stated that it had been successfully practised in this country by Dr. Trudeau, of Saranac Lake, New York.

DR. FREDERICK PETERSEN read a paper on

ANODAL DIFFUSION.

He said a more exact title for his paper would be "Electric Cataphoresis as a Therapeutic Measure." He spoke first of the remarkable series of experiments in voltaic narcotism for the production of local anæsthesia by Dr. Benjamin W. Richardson, as recorded in several papers published in the *Medical Times and Gazette*, during the year 1859. The fluid used in these experiments was composed of equal parts of tincture of aconite and chloroform, with the addition of a small quantity of alcoholic extract of aconite. Dr. Richardson had unfortunately abandoned the investigation of the matter soon after this, and it slumbered for more than twenty-five years. In 1886, Wagner published the excellent results which he had obtained in producing local anæsthesia by moistening the anode with a solution of cocaine, and the matter was then taken up by a number of observers. Among these was Dr. J. Leonard Corning, of New York, who published a new method of introducing the cocaine in the *New York Medical Journal* in November, 1886, but did not give any cases. Dr. Petersen exhibited the instrument invented by Adamkiewicz, which he criticised as unphilosophical in construction, and presented an apparatus which he had himself devised, and which he said had proved very satisfactory in his hands. He had made over one hundred careful experiments, and about one-fourth of these he briefly related. The medicinal agents which he had principally employed were cocaine and aconitia, and he had found the method very successful in a number of neuralgic and other painful affections. There could be no doubt, he thought, that cataphoresis was produced by this means.

DR. LANDON CARTER GRAY said that this was a new subject. He had got one of the Adamkiewicz instruments soon after they came out, and had obtained some results with it, but they were unfortunate results. He found its application quite painful, and in one case, where the patient was just recovering from an attack of acute articular rheumatism, he found that he had induced a second attack by the use of the instrument. Because of the painfulness of the carbon disk he had given it up, and since then whenever he had occasion to resort to this method he employed an ordinary sponge electrode.

DR. M. ALLEN STARR said that he considered this a very valuable method in the treatment of pain. In one of the cases cited by Dr. Petersen, where the patient was affected with locomotor ataxia, he had been a witness of the relief afforded. There was, however, one objection which he thought might be urged against this means of treatment, and that was, the uncertainty in the matter of dosage. It seemed to him that it would be possible, however, by a series of experiments, to arrive at some definite knowledge in regard to this point. On one occasion he desired to use aconitia by this method, but he hesitated because he feared that a dangerous amount of the drug might be introduced into the system. There was one other point which had not been brought out in the paper, and that was, the applicability of this method to diagnosis as well as to treatment. By the use of cocaine, for instance, it was possible, in a case of *tic convulsif*, to determine which branch of the trigeminal nerve was affected. The injection of cocaine was disagreeable and might cause abscess, and this method was, therefore, preferable to the use of the hypodermatic syringe. He thought the method might also be employed sometimes to determine whether the pain in a

given case was of peripheral or hysterical origin; since, if it were peripheral, it would be relieved.

DR. B. SACHS said that he had imported an Adamkiewicz instrument, but, after trying it for a time, he had not felt much encouraged to continue its use. In cases not very severe ordinary electric treatment gave as much relief, and, as a rule, he found that other means were quite as effective as this, such as the hypodermatic injection of morphia, cocaine, and aconitia. While he was impressed with the cases narrated by Dr. Petersen, he thought the latter should have appended other tests on the same patients. Thus, the same troubles that were treated by the method described should have been treated by the anode alone, and by the drug alone, pressed upon the skin for the same length of time. The method at best was only palliative, and not curative. He did not agree with Dr. Starr that it afforded a means of differential diagnosis between peripheral neuritis and hysterical pain, because hysterical pain was apt to give way at any moment.

DR. W. R. BIRDSALL said that he had had no practical experience with the method, but from the literature of the subject he had formed the opinion that it was of but little value. It seemed doubtful to him whether a sufficient amount of the medicinal agent employed could be introduced into the skin to cause the results claimed, and he was inclined to attribute whatever benefit was received in the cases in which it was tried to the anode alone. The depth to which such substances could be introduced has been said to be very slight; though in many cases all that was needed was simply to bring the remedy in contact with the absorbents of the skin. He was glad to learn, however, that Dr. Petersen had found the method of greater value than he had supposed it to be. Still, he thought many more experiments were required in order that one could decide positively as to its utility. Where the nerves were superficial he would suppose it to be of the most benefit. When asked if he had found it of service in sciatica, Dr. Petersen had told him that he had not, because the nerves were too deep.

DR. C. L. DANA said that he had obtained no satisfactory results with the Adamkiewicz instrument. Some time since Dr. Squibb had reported some very interesting experiments, in which decided results were produced by the local application of various substances, in connection with oleic acid, and with a preparation of it containing one per cent. of aconitia he had caused constitutional effects. No constitutional effects, however, had thus far been produced by the method in question, and he could not but agree with Dr. Birdsall, that it was very superficial in its action. With the use of Dr. Petersen's formula he had produced anæsthesia in only one out of three cases, though this might perhaps have been due to some defect in the technique employed.

DR. J. ARTHUR BOOTH said that Dr. Petersen's method certainly produced marked anæsthesia both to feeling and touch. As mentioned in the paper, one of the experiments recorded was made on his own person, and the anæsthesia lasted for at least fifteen minutes. For some time afterward the part experimented on remained very sore and hyperæmic. He had tried it himself on three cases, and in one it afforded decided relief.

DR. PETERSEN, in closing the discussion, said that he agreed with Dr. Starr, that the uncertainty of the dosage was one of the great objections to the method, but he thought it probable that by a course of experimentation, such as the latter had suggested, this difficulty would in time be obviated. As to Dr. Sach's criticism, that no parallel tests had been reported, he would say that in some of the cases the anode *was* used alone, and that no effects were observed except just at the time of its application. As to Dr. Birdsall's remark that the method was superficial in its action, and that the use of strong currents was required against strong resistance, in one or two of his experiments an imperceptible current, employed for a greater length of time, produced the same effects. There was, as had been said, an absence of constitutional effects, and as many of the experiments had been made upon his own person, he could speak with some degree of assurance on this point.

DIFFUSE PIGMENTATION PRODUCED BY THE INTERNAL USE OF ARSENIC.

DR. WM. M. LESZYNSKY exhibited a little girl nine or ten years of age in whom the use of Fowler's solution, given for the relief of chorea, had produced very marked pigmentation all over the surface of the body. There was no reason whatever to suspect the presence of Addison's disease, he said, and the case seemed to him a must remarkable one. As to the prognosis, as regards the permanency of the pigmentation, he was unable to express any opinion.

NEWS ITEMS.

The Harvard Medical School has just received from Dr. D. W. Cheever the sum of $5000 to establish a scholarship to be known as the David Williams Cheever Scholarship.

The Royal College of Physicians and Sir Morell Mackenzie.—At an ordinary meeting of the College held January 31, 1889, the following resolution was adopted: "That the judgment of the Censors' Board in the matter of the book by Sir Morell Mackenzie, entitled *The Fatal Illness of Frederick the Noble*, be received and adopted by the College, and communicated to Sir Morell Mackenzie."

The judgment of the Censors' Board was as follows:

"The attention of the Censors' Board having been directed to a publication by Sir Morell Mackenzie, entitled *The Fatal Illness of Frederick the Noble*, the Censors' Board, although unable to deal judicially with the various matters brought into dispute therein, feels called upon to express to the College its grave disapproval of the general character of the book, and its profound regret that one, whilst a member of this College, should have given, in any circumstances whatever, publicity to statements concerning his patient, and charges against his colleagues, injurious to the interests of the public, destructive of the confidence necessary between persons coöperating in the discharge of a great responsibility, and contrary to the traditions of the medical profession throughout the civilized world."—*British Med. Journal*, Feb. 9, 1889.

Floor-space and Ventilation of Schoolrooms.—MR. H. COURTHORPE BOWEN, who is well known as having given much attention to all questions concerning school management, gives the following as his experience of the requirements of a good schoolroom. Taking the

case of a room 14 feet high, fairly ventilated and always well aired in recess, he would assign two-thirds of the floor-space to the scholars and their desks, and keep the other third for the teacher, the blackboard, etc. With single desks 22 inches should be allowed from side to side, and 3 feet from back to front, for each scholar; the passages need not be more than 18 inches for those running from back to front, and 1 foot for those running from side to side. In such arrangement, counting the passages, each scholar has (without reckoning the share of the space allotted to the teacher) a trifle more than 40 inches from side to side, and just 4 feet from back to front. In a room 25 feet by 20 feet the floor-space for scholars' desks will be 16 feet by 20 feet, with 4 feet from back to front per row, and accommodation is provided for twenty scholars; the whole floor-space is 500 square feet, and the cubic contents of the room 7000 cubic feet, with 20 square feet and 280 cubic feet per person.

Such details from those whose daily work lies in the schoolroom are of value; the cubic contents allowed are such that continuous ventilation ought to be kept up by Tobin's tubes, or window ventilation; the space allowed between the rows of desks will suffice for school lessons, but is barely sufficient to allow of any calisthenic exercises without rearrangement of the room. It is hardly necessary to say that the floor-space here recommended is greatly in excess of that required by the Government in primary schools.—*British Med. Journal*, February 9, 1889.

NOTES AND QUERIES.

To the Editor of THE MEDICAL NEWS,

SIR: Please explain the Latin construction of "Tænia solium," and oblige Yours truly, QUIZ.

[We are not able to give a *certain* answer to our correspondent's question concerning *tænia solium*. It is not uncommon, in botany and zoölogy, when the name of a *genus* is feminine, for the specific name to be that of a noun, masculine or neuter. If that were the case in this instance, the only meaning possible for solium, as a noun, is bath-tub. Why this parasite should be called bath-tub tænia (riband, band, tape) we do not know.

Dunglison's statement that *solium* is from *solus*, alone (on the idea that this tænia is always solitary), seems improbable, both because solium cannot be correctly got from solus, and because, if the intention were to give that significance, the word would be an *adjective*, and ought to agree with the feminine tænia, being then *sola* (or, incorrectly, solia). This feminine is the form of the specific names of other species of tænia: tænia lata (old name), mediocanellata, etc.—ED.]

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 12 TO FEBRUARY 25, 1889.

By direction of the Secretary of War, leave of absence for two months is granted JAMES MCKEE, *Lieutenant-Colonel and Surgeon* (U. S. Army).—Par. 13, *S. O. 44, A. G. O., Washington*, February 24, 1889.

GREENLEAF, CHARLES R., *Major and Surgeon*.—Will proceed from this city as early as practicable to Newport Barracks, Kentucky, to examine and report upon a proposed change in the location of the post hospital at the new barracks now in process of construction near that post; thence to Columbus Barracks, Ohio, to examine and report upon the necessity for an addition to the hospital at that post.—Par. 16, *S. O. 43, A. G. O., Washington*, February 20, 1889.

LAUDERDALE, J. V., *Major and Surgeon* (U. S. Army).—Is granted leave of absence for one month, to take effect between March 1st and March 15th next.—Par. 2, *S. O. 9, Headquarters Department of Texas, San Antonio*, February 15, 1889.

BYRNE, CHARLES B., *Captain and Assistant Surgeon*.—Is granted leave of absence for twenty-one days.—*S. O 44, Headquarters Division of the Atlantic, Governor's Island, New York City*, February 21, 1889.

By direction of the President, ROBERT W. SHUFELDT, *Captain and Assistant Surgeon*, will proceed to Fort Leavenworth, Kansas, and report in person to Brigadier-General Wesley Merritt, President of the Army Retiring Board at that place, for reëxamination by the Board, and on the conclusion of his examination will return to this city.—Par. 13, *S. O. 40, A. G. O., Washington, D. C.*, February 16, 1889.

By direction of the Secretary of War, JAMES E. PILCHER, *Captain and Assistant Surgeon*, will repair from Fort Wood, New York Harbor, to Philadelphia, Pa., on or about February 23, 1889, for the purpose of giving instruction to the Hospital Corps of the First Brigade, National Guard of Pennsylvania; on completion of this duty, will return to his proper station.—Par. 1, *S. O. 41, A. G. O.*, February 18, 1889.

HARRIS, HENRY S. T., *First Lieutenant and Assistant Surgeon* (U. S. Army).—Will proceed to Fort Davis, Texas, so as to arrive there on or before February 25th, and report to the commanding officer thereof for temporary duty. Upon return of Surgeon Lauderdale from leave of absence, Assistant Surgeon Harris will return to the post of San Antonio.—Par. 3, *S. O. 9, Headquarters Department of Texas, San Antonio*, February 15, 1889.

By direction of the Secretary of War, the leave of absence on surgeon's certificate of disability, granted LEONARD Y. LORING, *Major and Surgeon*, in S. O. No. 6, January 18, 1889, Department of Arizona, is extended six months on account of disability.—Par. 23, *S. O. 35, A. G. O., Washington*, February 11, 1889.

By direction of the Secretary of War, FREDERICK C. AINSWORTH, *Captain and Assistant Surgeon*, will proceed to New York City and Brooklyn, N. Y., on public business.—Par. 15, *S. O. 38, A. G. O, Washington*, February 14, 1889.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING FEBRUARY 23, 1889.

RIXEY, P. M., *Passed Assistant Surgeon*.—Promoted to Surgeon, November 27, 1888.

BRADLY, GEORGE P., *Surgeon*.—Ordered to hold himself in readiness for duty about March 1st, to the "Mohican."

LUNG, GEORGE A., *Assistant Surgeon*.—Ordered to hold himself in readiness for duty about March 1st, to the "Mohican."

PERCY, H. T., *Passed Assistant Surgeon*.—Detached from Naval Hospital, Washington, and ordered to the Coast Survey Steamer "Patterson."

WHITING, ROBERT, *Passed Assistant Surgeon*.—Detached from the Coast Survey Steamer "Patterson," proceed home, and wait orders.

BERTOLETTE, D. N., *Surgeon*.—Detached from the "Thetis," and wait orders.

HENNEBERGE, L. G., *Passed Assistant Surgeon*.—Detached from the "Minnesota," and ordered to the "Thetis."

MARMION, R. A., *Surgeon*.—Detached from the "Juniata," and wait orders.

OGDEN, F. N., *Assistant Surgeon*.—Detached from the "Juniata," and wait orders.

STOKES, CHARLES F., *Assistant Surgeon*.—Ordered to the "Minnesota."

WILSON, GEORGE B., *Assistant Surgeon*.—Ordered to the Navy Yard, Mare Island, California.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE FOUR WEEKS ENDING FEBRUARY 23, 1889.

AUSTIN, H. W., *Surgeon*.—To proceed to Green Bay, Wisconsin, as inspector, February 9, 1889.

GUITÉRAS, JOHN, *Passed Assistant Surgeon*.—Granted leave of absence for sixty days, with permission to go abroad, February 13, 1889.

WHEELER, W. A., *Passed Assistant Surgeon*.—Orders to proceed to Cleveland, Ohio, revoked February 9, 1889.

DEVAN, S. C., *Passed Assistant Surgeon*.—To proceed to Charleston, South Carolina; Savannah, Georgia; and South Atlantic Quarantine Station, as inspector, February 9, 1889.

WASDIN, EUGENE, *Passed Assistant Surgeon*.—To proceed to Charleston, South Carolina, and assume charge of the Service, February 23, 1889.

DEATH.

URQUHART, F. M., *Passed Assistant Surgeon*.—Died at Evansville, Indiana, February 14, 1889.

HUNTING YELLOW FEVER GERMS.

An Address delivered by special invitation before the Quarantine Conference, at Montgomery, Ala., March 5, 1889.

BY GEORGE M. STERNBERG, M.D.,
SURGEON U. S. A.

GENTLEMEN: It would have been far more satisfactory to you and to me if the subject of my address this evening could have been announced as "The Yellow Fever Germ." I need hardly say that nothing would have given me greater pleasure than, in the presence of the experts in the clinical and prophylactic management of yellow fever here assembled, to exhibit microscopic preparations and pure cultures of the specific infectious agent which I have been so long in search of. I shall show you presently upon the screen photo-micrographs of a variety of microörganisms which I have encountered in the course of my researches, some of which are hitherto undescribed species, and among them some which have specially engaged my attention as possible yellow fever germs. I shall also show you cultures and photo-micrographs of the micrococcus presented to me by Dr. Domingos Friere, of Brazil, as his microbe of yellow fever; of the tetragenus febris flavæ of Dr. Carlos Finlay, of Havana; and of the bacillus of Dr. Paul Gibier, of Paris.

But I must announce to you, in advance, that there is no satisfactory evidence that any one of these micro-organisms is the veritable infectious agent in the disease under consideration.

I at first hesitated to accept the invitation extended to me to address you on this occasion, inasmuch as my investigations have not yet led to any definite result, and as they are still in progress and will be continued in Havana during the present summer. But the importance of the occasion and the solicitation of my good friend Dr. Cochran, the efficient Health Officer of the State of Alabama, have induced me to come here for the purpose of making a brief statement relating to the present status of the investigation with which I am charged, and especially for the purpose of demonstrating to you the methods of research employed by bacteriologists in investigations of this nature.

I may say before going any further, that my faith in a living infectious agent as the specific cause of this disease is by no means diminished by my failure thus far to demonstrate the exact form and nature of this hypothetical "germ." The present state of knowledge with reference to the etiology of infectious diseases in general, and well-known facts relating to the origin and spread of yellow fever epidemics, fully justify such a belief. The *a priori* grounds for such faith I stated as long ago as 1873, in a paper published in *The American Journal of the Medical Sciences* (July, 1873); and the progress of knowledge since that date has all been in the direction of supporting this *a priori* reasoning. But yellow fever is by no means the only infectious disease in which satisfactory evidence of the existence of a living infectious agent is still wanting. In the eruptive fevers generally no demonstration has been made of the specific etiological agent—at least none which has been accepted by competent pathologists and bacteriologists. Again, in the infectious disease of cattle known as pleuro-pneumonia, notwithstanding very extended researches by competent investigators in various parts of the world, no satisfactory demonstration of the germ has been made. The same is true of hydrophobia, in which disease we are able to say with confidence the infectious agent is present in the brain and spinal cord of animals which succumb to rabies; this infectious agent is destroyed by a temperature which is fatal to known pathogenic microörganisms (65° C.), and by various germicide agents, yet all efforts to cultivate it or to demonstrate its presence in the infectious material by staining processes and microscopical examination have thus far been unsuccessful.

You are aware that my first effort to solve the etiology of yellow fever was made ten years ago. As a member of the Havana Yellow Fever Commission of the National Board of Health, I had an opportunity to make researches which, in advance of the effort, I fondly hoped might lead to demonstration alike creditable to American science and useful as a basis for preventive and curative measures in this pestilential malady, which has destroyed the lives of so many of our fellow-citizens, and has so largely interfered with the material progress of certain sections of the United States. I knew, from personal experience, the malignant nature of the disease, and the futility of the various modes of treatment which had been resorted to in the effort to combat it. It was, therefore, with the deepest interest as well as with strong hopes of success, that I went to an endemic focus of the disease to search for the yellow fever germ. The recent (1873) demonstration of the spirillum of relapsing fever in the blood of patients suffering from this disease, and the recognized facts relating to the etiology of anthrax, considered in connection with the current notions relating to the pathology of yellow fever, led me to hope that the discovery would prove an easy one. I was familiar with the most approved methods of mounting and staining microörganisms, and was provided with the best high-power objectives that could be procured, the one-twelfth and one-eighteenth homogeneous oil immersion objectives of Karl Zeiss, of Jena, Germany. Not only did I feel that I was equipped for the recognition of any micro-organism which might prove to be present in the blood, but I was prepared to photograph it, and thus to show to others what I might see in blood drawn from the circulation of yellow fever patients. You know the result of this investigation; "ninety-eight specimens from forty-one undoubted cases of yellow fever were carefully studied, and one hundred and five photographic negatives were made, which showed satisfactorily everything

demonstrable by the microscope." But no microörganism was discovered. I shall presently show you upon the screen a photo-micrograph of yellow fever blood, made in Havana at the time mentioned, so that you may judge of the performance of my Zeiss one-eighteenth inch objective, and have ocular evidence that no microorganism demonstrable by this magnificent lens was present in it. I may say here that my culture experiments, made in Havana last spring, in which blood taken from one of the cavities of the heart, as soon as possible after death, was introduced into various nutritive media, gave a like negative result.

Out of ten cases in which I made autopsies, in the military hospital at Havana, a development of microorganisms occurred in two only. In the exceptional cases I obtained a bacillus which subsequent researches showed to be identical with a bacillus constantly found in the alimentary canal of healthy persons—the *bacterium coli commune* of Escherich.

The absence of microörganisms from blood drawn from the finger during life, or from the heart after death, cannot, however, be accepted as evidence that there are no parasitic organisms anywhere in the tissues. The bacillus of typhoid fever, for example, is rarely found in the circulating fluid, although it must be transported in the blood current to the various organs in which foci of growth are found which contain numerous bacilli. Such foci are especially abundant in the spleen, but even in this organ many thin sections may be made before a single focus of development is encountered.

Having failed to find the yellow fever germ in the blood, we may still admit that, as in typhoid, it is perhaps only to be found in the organs principally involved in the morbid process. This reasoning has led me to give special attention to an examination of the liver and kidney, both by the culture method and by the examination of thin sections. Both methods have given me positive results, so far as the occasional presence of microörganisms is concerned, but both are in accord in failing to demonstrate the constant presence of any particular organism. In my culture experiments, made in Havana last year, the microörganism most frequently encountered was my bacillus *a*, already referred to as found in two out of ten cases in cultures from blood drawn from the heart. Naturally, I have given much attention to this bacillus, and it was only after an extended series of comparative experiments that I gave up the hope that it might be concerned in the etiology of the disease under consideration. These comparative experiments forced me to the conclusion that this is the same bacillus as was found by Emmerich in cholera cadavers at Naples, and that it corresponds with the *bacterium coli commune* of Escherich.

In my researches by the method of staining thin sections of the tissues hardened in alcohol, I have encountered several different microörganisms; but no one of these has been found in a series of cases. One, the bacillus of Lacerda and Babes, I have found only in material brought from Dr. Lacerda's laboratory in Brazil, and in two only out of nine cases represented by material from this source. In one of my Havana cases, in which the material was collected by my friend, Dr. Burgess, in 1887, a long bacillus was found in the kidney, for the most part in the glomeruli. In a case in which I made the autopsy in Havana last spring a micrococcus, grouped in fours, was found in the kidney.

Evidently, if any one of these microörganisms was found in a considerable series of cases, the fact would be decidedly significant, and would afford presumptive evidence that the parasitic organism found bore some relation to the morbid process. But, even if one and the same microörganism was found in every case, the final proof of its etiological import would depend upon its isolation in pure cultures, and the production of the characteristic phenomena of the disease in one of the lower animals, or, in the absence of a susceptible animal, in man himself.

The method of cultivation is by far the most reliable for the demonstration of microörganisms which will grow in our culture media, for isolated cocci or bacilli might easily escape observation when present in small numbers but would serve to start a culture. Thus the bacillus of typhoid fever, which, as stated, is not as a rule found in the blood of the general circulation, and is only found in the spleen in scattered clumps, may be obtained from this organ in pure cultures, almost without fail, by introducing a small quantity of splenic pulp into a suitable nutritive medium.

Moreover, this method enables us to differentiate microorganisms which look alike, and which by microscopic examination alone it would be impossible to distinguish one from another. This is a fact now well recognized by bacteriologists, but not generally appreciated by microscopists whose researches have been limited to the staining and mounting of sections.

Both methods require skill and practice in the execution and great caution in drawing conclusions, for there are a thousand traps lying in wait for the explorer, in this field of investigation. It is for this reason that pseudo-discoveries are so numerous.

Especial care is required in the microscopical examination of stained preparations of yellow fever tissues. One encounters in the urinary tubules, mingled with the débris of the desquamated epithelium, stained masses of various forms which often closely resemble cocci or bacilli. These I believe to be fragments of nuclear material. The same material is often massed in the urinary tubules in the form of plugs, which are deeply stained by the aniline dyes.

Again, fragmentation of the nuclei of cells still in position may give the impression of a cell containing cocci; and the karyiokinetic figures found in the cells, especially in the liver, often resemble bacilli so closely that it is difficult to convince any one not familiar with them that they are not microörganisms.

The "plasma cells" of Ehrlich, also, seem to have as their chief function the *rôle* of deluding amateur microscopists into the idea that they have made a discovery. They are often very abundant in the liver and in the kidney of yellow fever cases, and so closely resemble zoöglœa masses of micrococci that experienced pathologists have been deceived by them.

In addition to these objects which resemble microorganisms there are dangers from the post-mortem invasion of the tissues when the autopsy has been delayed beyond an hour or two, in the warm climates where yellow fever prevails; or even in the preserving medium, or during the process of staining.

My experiments made in 1883 showed that "exposure

to ninety-five per cent. alcohol for forty-eight hours did not kill the bacteria in broken-down beef-tea (old stock)," and pathologists are familiar with the picture presented by the post-mortem invasion of tissues which have been left in alcohol which was not strong enough to preserve them.

Finally, inasmuch as my culture experiments with material collected soon after death, from the liver and kidney, gave a positive result in a certain proportion of the cases, it is evident that the microörganism most frequently found by this method—my bacillus *a*—should occasionally be encountered in stained preparations.

The possibility remains that by some method of staining not hitherto employed, the specific infectious agent may yet be demonstrated in the tissues; but the fact that my culture experiments with material from the liver and kidney of ten cases failed to demonstrate any such specific microbe is opposed to this view. We may, of course, suppose that the yellow fever germ not only requires special methods, yet undiscovered, for its demonstration in the tissues, but that it will not grow in the culture media which I have employed in my researches. I would say in reply to this hypothesis that all known pathogenic microörganisms may be demonstrated by the staining methods employed, and that, inasmuch as the yellow fever germ appears to find a favorable nidus in filth beds external to the body, I have been inclined to believe that, like the bacillus of typhoid fever and cholera, it is not especially nice as to the character of the medium in which it may develop. However, this may be a mistaken idea, and I propose in my future researches to make use of various culture media not yet employed, and especially to make cultures from the tissues and the excreta in an atmosphere from which oxygen has been excluded; for it may be that, like the bacillus of malignant œdema and the bacillus of tetanus, the yellow fever microbe is anaërobic.

While, then, I admit that by some special method of staining, or by a modification of the culture methods heretofore employed, the specific infectious agent we are in search of, may yet be found in the tissues of yellow fever patients, I feel justified in saying that no such demonstration has yet been made. The negative results attending my researches in this direction have led me to turn my attention to the microörganisms present in the alimentary canal, for the possibility suggests itself that this may be after all the habitat of the deadly yellow fever microbe, which is capable of destroying life within two or three days, and that the phenomena of the disease are not directly due to its presence in the body, but result from the absorption of a poisonous ptomaine produced by it, as appears to be the case in cholera.

The famous English hygienist Parkes, from the consideration of evidence relating to the prevalence of yellow fever during a series of years among English troops stationed in Jamaica and elsewhere within the "yellow fever zone," in connection with the sanitary condition of their barracks, arrived at the conclusion that yellow fever is a "fecal disease," and there are many facts relating to the origin and extension of epidemics which seem to support this view—that is, the belief that the germ finds a proper nidus in fecal matter external to the body. If in yellow fever, as in cholera, the infectious agent is located in the alimentary canal of those who fall sick with the disease, we can readily understand how it is that new centres of infection are developed, when external conditions are favorable, in the localities where imported cases have occurred, or as a result of the introduction to such localities of fomites.

This view also accords with the demonstrated fact that yellow fever is not directly communicated by the sick to those in attendance upon them. Pathogenic germs which multiply in the intestine no more endanger those who are associated with the infected individual than the same microörganisms cultivated in a suitable medium in a test tube endanger the bacteriologist who is engaged in their study.

The possibility that the infectious agent in yellow fever may have its habitat in the alimentary canal, occurred to me several years ago, and I determined, in advance of my visit to Havana last spring, to give special attention to a bacteriological study of the intestinal contents.

It is well known that the excreta of healthy persons contain a vast number of microörganisms of various species, and that while some of these appear to be constant, others are occasional, and, we may say, accidental tenants of the human intestine, being introduced, no doubt, with the ingesta, and especially in drinking water.

Notwithstanding the researches of Brieger, of Bienstock, of Escherich, of Vignal, and others, this bacterial flora of the healthy intestine is still imperfectly known. The attempt, therefore, to explore this field for the purpose of finding a specific microbe in any particular disease, is attended with very great difficulties, unless, as in cholera, this specific microbe occupies the field to the exclusion of the ordinary bacteria found in the intestinal contents. Koch found his "comma-bacillus" almost in pure cultures in the characteristic rice-water discharges of cholera patients, and other bacteriologists, following his methods, have had no difficulty in verifying the presence of the same microörganism in cases of cholera occurring in various parts of the world. On the other hand, extended comparative researches, including my own investigations made in Havana and in Decatur, show that the "comma-bacillus," or rather spirillum, is not found in the alvine discharges of healthy persons, or in other diseases than cholera. If in yellow fever, as in cholera, there was a microörganism in pure cultures, or in relatively great abundance, capable of growing in the culture media which are suitable for the development of a majority of the known pathogenic organisms, I ought to be able, to-night, to exhibit to you cultures and photomicrographs of this microörganism. But my researches show that the microörganism which is by far the most abundant, and, so far as my investigations go, the only constant form found in the excreta of yellow fever cases, is the *bacterium coli commune* of Escherich, which is also the most constant and abundant form found in the excreta of healthy persons.

In Havana my cultures were made from material from the stomach and intestine of fatal cases obtained at the time of making the autopsy. My researches did not show that any of the microörganisms encountered was constantly present, with the exception of the *bacterium coli commune*—my bacillus *a*. Having excluded this bacillus by comparative researches, there was nothing to point to any one of the microörganisms present in my cultures as the probable infectious agent I was in search of.

The bacillus of Dr. Paul Gibier I only encountered in three cases out of ten, and in these it was not present in

very great abundance, compared with the colon-bacillus for example.

My time in Havana, limited by my orders, was too brief to enable me to make an exhaustive research. The epidemic in Florida and Alabama during the past summer gave me an opportunity to continue the investigation, and, at my request, I was directed to proceed to the infected district for this purpose. The presence of my friend Dr. Jerome Cochran, State Health Officer, at Decatur, decided me to locate my laboratory in that place, where I found abundant material for the researches I had in view. Having made a considerable number of autopsies in Havana, I determined while in Decatur to devote my attention especially to a bacteriological study of the alvine discharges collected during the different stages of the disease.

Evidently, if the infectious agent multiplies in the intestine, it should be found in the excreta during the earlier stages of the attack.

The cause must be present in advance of the development of the morbid phenomena which characterize the disease. But it is quite possible that during its later stages the etiological agent has perished, and, therefore, would not appear in cultures made from material obtained post-mortem.

While in Decatur, and after my return to Baltimore, I examined by bacteriological methods—Esmarch tubes—the excreta of 39 cases of yellow fever, and for comparison of 9 convalescents and of 19 healthy individuals. A detailed account of the results reached will be given in my final report. As was to have been expected, I have encountered a variety of microörganism. Many of these I have isolated in pure cultures, and the biological and pathogenic characters of several have been carefully studied by cultivation in various media and by inoculation experiments in the lower animals. It would be premature for me to attempt to give you the results of these researches even if time permitted me to do so. But I may repeat what I said at the outset that the germ of yellow fever has not yet been demonstrated. It is possible, however, that one or the other of the microörganisms which I have isolated is the long-sought germ, although I have no satisfactory evidence upon which to base a claim that this is the case.

My attention has been especially directed to the liquefying organisms found in the excreta of the 39 cases examined. In a majority of these cases the presence of liquefying bacilli was demonstrated, but liquefying colonies were not numerous as compared with the non-liquefying, among which the colon-bacillus of Escherich was by far the most abundant. In a series of Esmarch tubes No. 1 would show numerous liquefying centres, usually within twenty-four hours, very often No. 2 would contain a few liquefying colonies, while, as a rule, No. 3, although containing numerous isolated colonies of the colon-bacillus, did not contain any liquefying colonies. Further, I found that several different liquefying organisms were present in different cases, or were associated in the same case. I shall presently show you cultures and photomicrographs of these liquefying bacilli. The one most frequently present, my bacillus *o*, I have since found in cultures from another source, and am obliged to exclude it as the possible specific etiological agent of yellow fever. It has also been isolated by Dr. Booker, of Baltimore, from the discharges of one or more infants suffering from summer diarrhœa. The bacillus of Gibier I have only isolated from three cases, and in these it was not present in considerable numbers. I have made extensive experiments upon the lower animals, which show that this bacillus has interesting pathogenic properties, but give no special support to the view that it is the specific germ of yellow fever. I have never observed in my cultures the black pigment which, according to Gibier, is produced during the development of this bacillus, and am at a loss to understand this discrepancy in our observations.

So far as the pigment in black vomit is concerned, I have no doubt that it is of hæmic origin. I have never failed to demonstrate, by a microscopic examination, the abundant presence of red blood-corpuscles in the numerous specimens of black vomit which I have examined. The little black flocculi are, in fact, made up of agglomerated corpuscles which have lost their pigment and appear as pale disks, often more or less swollen and distorted; while the brownish pigment, which has been changed by the acid secretions of the stomach, remains in their vicinity in the form of granules or amorphous masses. The idea that there is something specific about this pigment, or that it is the secretion of a specific microbe, as has been maintained by Freire and by Gibier, appears to me to be untenable. In a majority of the non-fatal cases of yellow fever and in a certain proportion of the fatal cases there is no passive hemorrhage into the stomach, and consequently no black vomit, yet these cases must result from the action of the same etiological agent as those in which this symptom is present.

I have found by experiment that the bacillus of Gibier, the micrococcus of Freire, and the tetragenus of Finlay, all grow after being exposed for an hour to a temperature of $-15°$ C. (5° F.). Exposure outside of the laboratory in Baltimore for five days in the month of January failed also to destroy the vitality of these microörganisms, although the temperature, during the greater part of the time at least, was below the freezing-point.

Having thus given you a brief account of the present status of the investigation in which I am engaged I propose to devote the remainder of the time at my disposal to a practical demonstration of the methods of research employed, and to an exhibition upon the screen of the various microörganisms to which I have referred.

ACUTE PANCREATITIS.

A Consideration of Pancreatic Hemorrhage, Hemorrhagic, Suppurative, and Gangrenous Pancreatitis, and of Disseminated Fat-necrosis.

The Middleton-Goldsmith Lecture for 1889, delivered before the New York Pathological Society, Feb. 16, 1889.

BY REGINALD H. FITZ, M.D.,

SHATTUCK PROFESSOR OF PATHOLOGICAL ANATOMY IN HARVARD UNIVERSITY AND PHYSICIAN TO THE MASSACHUSETTS GENERAL HOSPITAL.

(Continued from page 230.)

SUPPURATIVE PANCREATITIS.

IN order to more fully appreciate the relation which hemorrhagic pancreatitis may bear to pancreatic inflammation and hemorrhage, it becomes necessary to consider the evidence in favor of other varieties of acute pancreatitis. Although the authorities of the present

day make but little mention of a suppurative inflammation, Lieutaud[1] in the last century alludes to cases of pancreatic abscess reported by Bartholinus, Tulpius, Aubert, and Patin.

To these may be added those of Riolanus, Bons, and Gautier, referred to by Ancelet.[2] Clässen[3] states that Blanchard, in 1688, described the occurrence of small, purulent points on the surface of the pancreas of a child who died of smallpox. Also that Tonnellé found a suppurating pancreas in two cases of puerperal fever. But the cases thus referred to are almost invariably of but little value for purposes of comparison. Döring,[4] for instance, found the enlarged and indurated pancreas connected with an abscess in the mesentery of the transverse colon, which held some four ounces of offensive, yellow pus, apparently proceeding from the pancreas. But the evidence is wanting to show that the pancreas was the source of the disease.

Portal[5] saw the pancreas soaked in pus in the body of a man who died after a violent attack (of gout?). Again,[6] he found the contents of the abscess often enclosed, as in a pocket, in a membranous sac formed by the cellular tissue which covers the pancreas. He declares that he has seen more than a quart (*deux livres*) thus enclosed. Here again the question may be raised as to the nature of the abscess and its relation to the pancreas. His mention[7] is worthy of note, of the man who died after extirpation of the testicle and ligature of the spermatic cord. A large quantity of pus was found in the cord, and a considerable abscess around the pancreas.

It is supplemented by the case reported by Moore,[8] of a young man who was seized with a sudden, abdominal pain which in the course of twenty-four hours became worse, and fixed in the right iliac fossa. There were vomiting, constipation, and chills. For several days the patient was not confined to his bed, but he died on the nineteenth day. The diagnosis was typhlitis. The perforated vermiform appendix led into an abscess which had penetrated the iliac muscle and communicated with the cæcum.

There were one large and several small abscesses in the pancreas. The two main veins were filled with thrombi; there was a portal thrombosis continued to the liver, and a parietal thrombosis of the vena cava.

There were numerous small abscesses in the brain.

The case reported by Percival,[9] as of pancreatic abscess, must be regarded as of somewhat doubtful nature. A man of middle-age was sick for three months with jaundice, bilious vomit, and a hard epigastric tumor.

Blood and finally fetid pus were discharged from the bowels. Eventually anasarca occurred. The epigastric tumor proved to be the greatly enlarged pancreas, which was scirrhous, and contained a considerable abscess.

The common duct was impervious from the pancreatic pressure, and the liver was "much diseased."

Andral[10] found two small abscesses in the middle of the pancreas.

[10] Précis d' Anat Path., 1829, ii. 582.

In order to determine the relative frequency of suppurative pancreatitis, the conditions of its occurrence, its symptomatology and results, the following thirty-two cases have been collected.

Case XXXIV.—Male, aged twenty. General abdominal pain, nausea, sense of distention and weight in stomach after eating. Tendency to purge. Dropsy. Pancreas a good deal enlarged, and contained a considerable quantity of pus.—Baillie. *Morbid Anat.*, 1833, 221, 223.

Case XXXV.—Male, adult. Feeble, scrofulous, phlegmatic. Dull epigastric pain for several weeks, then becoming violent, with nausea, offensive, loose stools, quick pulse, dry skin, sensitive epigastrium. Temporary improvement. Return of diarrhœa, fever, emaciation, weakness. Death at end of more than four months. Pancreas in part hardened, in part full of pus. The pus had escaped into the abdomen. Other organs normal.—Perle. *De pancreate ejusque morbis.* Diss. Inaug., Berl., 1837, 33.

Case XXXVI.—Adult. Corpulent, apparently much addicted to food and drink. Great epigastric pain, distention after meals, continued dull pain extending into both hypochondria above navel, relieved by purgatives, vomiting, constipation. Progressive emaciation and debility. Stools finally fetid, bloody. Temporary improvement, hectic, and death after nine months of illness and four in house. Intestinal obstruction suspected. Enlarged pancreas formed a purulent mass without healthy structure. Its extremity had ulcerated into the duodenum at lower curvature, through which pus must have passed into the intestine. Liver enlarged, spleen normal.—Fletcher. *Prov. Med. and Surg. Journ.*, Lond., 1848, 20.

Case XXXVII.—Male, aged forty-one. Indolent; large eater, fond of sweets. For some years attacks of bilious dyspepsia. Last attack seven months ago; did not recover as usual. Emaciated, feeble, dispirited, restless; frequent vomiting, eventually of thin, ropy mucus. Sensation of distended stomach and bowels, in which there was much gas. No appetite, no thirst, sluggish bowels, consistent stools, unmixed with bile and very fetid. No pain nor sensitiveness, nor tumor. Left abdomen dull; tympany in right abdomen and over stomach.

After two months of slight downward tendency, frequent chills and fever. Region between navel, lower border of stomach, and left flank dull, doughy, inelastic, not sensitive. After two weeks, chills ceased and a resistant sore spot appeared above navel and at the left. Œdema of feet and legs. Death after eleven months. Pancreas much enlarged, envelopes thickened. Entire gland formed a trabeculated cavity filled with creamy pus and a few cheesy masses about the size of a bean. The duodenum contiguous to the pancreas broke into pultaceous shreds, even on cautious handling. Spleen enlarged one-third. Despite extreme emaciation, a half-inch of fat in the abdominal wall.—Kilgour. *London Journal of Medicine*, 1850, ii. 1052.

Case XXXVIII.—Female, aged fifty-four. Robust. Some months ago, an attack of disturbed digestion with loss of appetite, flesh and strength, chilliness, morning belching, thin, viscid, liquid vomit. Recovery. Recurrence of antecedent symptoms, with deep-seated, dull pain, pyrosis, slight jaundice, swollen epigastrium. Alternate diarrhœa and constipation; stools white, slimy, not offensive. Gradual loss of flesh and strength. Death. Pancreas wholly suppurating. Spleen natural. Gall-bladder full of bile.—Riboli. *Gazz. Sard.*, 1858. Schmidt's *Jahrb.*, 1859, cii. 177.

Case XXXIX.—Female, aged sixty-four. Upper part of pancreas a dense, gray callus, in which a few remains of gland substance and round cavities, up to the size of peas, filled with thick white fluid; also several small pus cavities. In the lower part of the pancreas an abscess as large as a walnut. The duct, narrowed at the mouth, gradually widened toward the tail. Posterior

wall of the stomach firmly adherent to pancreas, and contained a submucous abscess.—Klob. *Œster. Zeitschr. f. pr. Heilkde.*, 1860, vi. 529.

CASE XL.—Male, aged twenty-three. Well. Severe gastric pain without cause, loss of appetite, sluggish stools, slight fever, sensitive epigastrium, rapid emaciation. In the course of a fortnight, violent paroxysms of stabbing pain spreading laterally from the epigastrium, which was swollen, tense, and tympanitic. Paroxysms attended with transient collapse. In the fourth week, a feculent diarrhœa, which suddenly became thin, profuse, watery, with nausea and bilious vomit. After decided improvement, fever and diarrhœa returned in the seventh week, and the abdomen became much distended. The tympany increased; there were occasional hiccough, progressive weakness, extreme emaciation, and death on the sixty-fifth day. Pancreas large, firm, yellowish-red. Sclerosis of peripancreatic tissue. On section several abscesses, some larger than a bean, at times communicating by sinuous tracts, two of which opened into the adherent posterior wall of the stomach, and two into the duodenum, Spleen of normal size, firm, pale red. Splenic vein obstructed by a reddish-yellow thrombus, in front of which the vein-wall was shreddy and its cavity communicated with a large abscess. A lumbricus lay half in the vein and half in the abscess, and in a sinuous passage leading from it to the duodenum. An abscess as large as a hen's egg in the left lobe of the liver. Fibrinous peritonitis, especially in upper abdomen.—Drasche. *Ber. d. k. k. Kranhenhauses. Rud.-Stift in Wien*, 1868, 301.

CASE XLI.—Male, aged thirty. Intemperate, much exposed when drunk, and then had dyspnœa. Had had two attacks of intermittent fever. Chronic cough for two years. Under treatment for syphilis. After two days of constipation, slight epigastric pain and vomiting, thirst, hot skin, no appetite. The bowels were moved freely. A chill occurred, followed by fever, chills, and diarrhœa toward the end of the week, then slight jaundice, persistent chills, and diarrhæa, and death in collapse on the twelfth day. Pancreas firmly adherent, On section of the enlarged head an abscess opened, the walls thick; contents, an ounce of pus. The dilated duct in the head held several calculi. Spleen weighed eleven and one-half ounces. Lungs phthisical, and containing a central chocolate-colored nodule, from which pus escaped.—Roddick. *Canada. Med. Journ.*, 1869, v. 385.

CASE XLII.—Male, aged twenty-five. Catarrhal symptoms and great debility for two weeks. For two days gastric irritability, nausea, constipation. Then incessant hiccough, epigastrium distended, tympanitic, no pain, no tenderness, constant copious vomiting of thin, brownish, stringy fluid, no jaundice, increasing loss of flesh and strength. Death from exhaustion in six days from the onset of the symptoms of gastric disturbance. Diagnosis, ileus. Pancreas large, head indurated, mortar-like. Duodenum closed by pancreatic pressure, coats thickened. Small omental hemorrhages. Distended gall-bladder.—Nathan. *Med. Times and Gaz.*, 1870, ii. 238.

CASE XLIII.—Male. Pancreas closely connected with neighboring organs. Splenic end contained a small abscess, with thick, greenish-yellow pus. Several small lymphatic glands near duodenal end contained similar pus. Abscess in the diaphragm above the spleen.—Smith. *Dublin Journ. Med. Sci.*, 1870, 201.

CASE XLIV.—Male, aged thirty. Continued fever, severe abdominal pain at level of spleen, which was supposed to contain an abscess; death in a month. Abscess of pancreas, surrounded with adhesions.—Frison. *Marseille Méd.*, 1875, xii. 257.

CASE XLV.—Male, aged twenty-eight. Delicate, suffered from hard work and extra hours. Loss of appetite, epigastric pain, jaundice, no fever. In third month, pain in right hypochondrium and shoulder; swollen abdomen, testicles, and feet. Sudden increase of appetite and thirst, abundant saccharine urine. In the tenth month intense jaundice, extreme emaciation, great weakness, lower abdomen dull, upper abdomen distended and tympanitic. Diabetes persisted, return of fever. Death in coma, at end of ten and a half months. Pancreas enlarged threefold, indurated, infiltrated with pus. A large collection of thick, yellow pus in the tail. Numerous small abscesses in the left lobe of the liver. Enormous dilatation of the common bile-duct. Spleen not enlarged.—Frison. Loc. cit.

CASE XLVI.—Male, aged forty. An attack of severe abdominal pain, without cause, followed by tense tympanitic abdomen, which was sensitive. Frequent regurgitation and bilious vomit, constipation, high fever. Death in the course of a week. Pancreas enlarged threefold, reddened, consistency increased, studded with hundreds of abscesses up to the size of beans, many projecting, had burst into abdomen. General fibrino-purulent peritonitis, especially in the upper abdomen.—Friedreich. *Zeimssen's Handb. d. sp. Path. u. Ther.*, 1875, vii. 2. 243.

CASE XLVII.—Male. Strong, temperate. Dislike for fatty food. Sick headaches, left inguinal hernia. After a month of cough and dyspnœa, six months ago, came diarrhœa, wasting, loss of appetite, and jaundice. After seven weeks, a month of considerable œdema. For ten days, epigastric and interscapular pain. Death from exhaustion, after five months of abdominal symptoms. Head of pancreas enlarged. A diffuse abscess followed the course of the ducts and opened into the lesser mental cavity, which was full of pus, and communicated with the duodenum. Fibrino-serous peritonitis. Thrombosis of femoral vein. Cheesy apices, cirrhotic liver, distended bile-ducts.—*St. George's Hosp. Rep.*, 1877-'78 '79, ix. 95.

CASE XLVIII.—Female, aged twenty-nine. Fifteen months ago, pain in region of liver, increasing and shooting, no nausea, poor appetite, bowels regular, feces dark. Jaundice for two weeks, tenderness over gall-bladder, cough, disturbed sleep. After two weeks, apparent convalescence for four days, then return of pain over gall-bladder, nausea, bilious vomit, jaundice, restless, rapid breathing, unconsciousness; death in thirty-six hours. The enlarged and hard pancreas contained an abscess. A round worm, seven inches long, lay partly in the duodenum, partly in duct. Large fatty heart, pale kidneys. Large, pale, soft liver.—Shea. *Lancet*, 1881, ii. 791.

CASE XLIX.—Male, aged fifty-eight. A year ago, loud belching, abdominal fulness, no sensitiveness. Nine months ago pale, sensitive epigastrium; black, tarry stools. Recovered from these symptoms, but was pale and emaciated. After five months, another attack of intense gastric disturbance, lasting a fortnight. Then improvement and gain in weight. After an error in diet, vomiting and severe abdominal pain. Swollen, sensitive abdomen. Pains in both hypochondria. After four days, increasing meteorism, fever, return of vomit, sleepless, progressive weakness, collapse, and death on the eleventh day. Pancreas swollen, anterior surface dotted with numerous yellowish-white prominences up to the size of hemp-seed, alone and in groups, forming cavities with smooth walls and pap-like contents. A group of these gray, gangrenous, covered with shreddy peritoneum. The contents of these cavities were partly granular corpuscles and detritus. The smallest had a wall of small-celled infiltration, similar foci on sections, also narrow and broad bands, and diffused growth of fat tissue. Similar prominences in the transverse mesocolon and mesentery; in the former a circumscribed necrosis with floating shreds and fresh peritonitic adhesions. Abundant sub-peritoneal fat.—Fränkel. *Zeitschr. f. klin. Med.*, 1882, iv. 277.

CASE L.—Male, aged twenty-five. Obscure symptoms

of peritonitis. Pancreas extensively destroyed by suppuration. The remaining splenic end, infiltrated with pus, showed a ragged surface, forming part of the wall of an abscess, bounded below by the lowest four inches of the ileum, and above by the stomach, spleen, abdominal wall, and coils of intestine.—Moore. *Trans. Lond. Path. Soc.*, 1882, xxxiii. 186.

CASE LI.—Male, aged seventy-four. Head of the pancreas, partly broken down, formed one wall of an abscess; elsewhere bounded by peritoneal adhesions.—Moore. Loc. cit.

CASE LII.—Male, aged thirty-five. Slight jaundice. A large part of the head of the pancreas destroyed by an abscess bounded by pancreas, duodenum, and under surface of stomach. The dilated common duct communicated with the abscess, and the latter opened into the peritoneal cavity and eroded the pancreatico-duodenal artery.—Moore. Loc. cit.

CASE LIII.—Male, aged forty-two. Intemperate, exposed to hardship. For some weeks increasing debility. One attack of vomiting, marked ascites. For the next twenty-five days, dull, listless, without appetite, fever, pain. Ill-defined epigastric tumor, not sensitive. Abdomen tapped, refilled in eighteen hours. In the head of the pancreas an abscess as large as an orange. The rest of the gland dense, containing numerous pus pockets. Ducts dilated. The large abscess opened into a pus-cavity, bounded by posterior wall of stomach, pancreas, duodenum, transverse colon, and peritoneum. Portal vein filled with a puriform thrombus extending into hepatic, splenic, and mesenteric veins. Slight cirrhosis, small, soft spleen. Recent peritonitis, bronzed skin.—Musser. *Amer. Journ. Med. Sciences*, 1886, N. S., xci. 449.

CASE LIV.—Male, aged twenty. Ate a probably putrid sausage; sudden nausea, violent vomiting, prostration, alternating heat and cold, severe headache. The next day, chill, cutting pains in abdomen, diarrhœa. On the fifth day, high fever, meteorism, dilated gastric and ileo-cæcal regions. A week later, jaundice. After five days the liver became enlarged, painful, and sensitive; the abdomen eventually distended and tense, the stools thin and pap-like; urine frequently contained peptones; one or two daily chills, with atypical and abrupt changes of temperature. Eventually repeated watery vomit, hiccough; death in collapse, at the end of the sixth week. Head of the pancreas contained an abscess as large as a hen's egg, filled with greenish-yellow pus. The greatly enlarged liver agglutinated to the diaphragm, anterior abdominal wall, and stomach; numerous abscesses present, the largest the size of a hen's egg; also dark violet nodules. Vena portæ almost obstructed by a brownish-red thrombus continued into the splenic vein. Behind the pancreatic abscess the portal vein wholly obstructed, the thrombus reddish-gray, in a state of puriform softening. Spleen six by three and a half inches; pulp not readily scraped away, dense, brownish-red. Recent fibrino-serous peritonitis.—Bamberger. *Wiener klin. Woch.*, 1888, xxxiii. *Allg. med. Centr. Zeit.*, 1888, lvii., 1870, 1886.

CASE LV.—Female, aged thirty-nine. Intemperate. Has suffered for a year or two from poor appetite, distress after eating, pain in the stomach, constipation. Sudden epigastric pain, vomiting, constipation; in the course of a few days, after an error in diet, the pain became intense, accompanied with fever. There were constant hiccough and vomiting. The abdomen became swollen and the epigastrium sensitive. The constipation persisted, and intestinal obstruction was suspected. Six days before death, after indulging in alcohol, his symptoms became aggravated, and death occurred on the forty-eighth day. The head of the pancreas contained a trabeculated cavity with green, shreddy walls, which communicated with the parapancreatic fat tissue; a branch of the duct with green and friable walls opened into the cavity. In the fat-tissue at the splenic end of the pancreas was a cavity containing a dirty-green fluid. Multiple nodules of fat-necrosis are present; also peritoneal adhesions between the stomach and transverse colon in the omental bursa. No general peritonitis. Nothing abnormal in the portal vein or its branches.—*Mass. Gen. Hospital Records* and MSS. Notes, 1888, v. p. 131.

They are twenty-two in number. One was of recent occurrence in Boston, for the notes of which I am indebted to Drs. Sears, Thompson, Jones, and Whitney.

The more detailed history of Case LV. is as follows: The patient was thirty-nine years of age, rather fat, intemperate. For a year or two before her fatal illness she had suffered more or less from poor appetite, distress after eating, wind in the stomach, and costiveness.

She was seized with sudden epigastric pain, without known cause, followed by vomiting, and the bowels were constipated. On the following day the pain became worse, but was somewhat relieved after vomiting. The next day, after a dinner of roast goose and cabbage, the pain became much aggravated. It was intense on the fourth day, and there were constant hiccough and vomiting. The epigastrium was sensitive and the abdomen swollen. Pulse 120; temperature 103.4° F. She remained in this condition for several days without any movement of the bowels, and intestinal obstruction was suspected. Castor oil finally produced a dejection which was followed by a lowering of the pulse and temperature.

For nearly a fortnight she was not seen by a physician, and she was then admitted to St. Monica's Home, where she remained two weeks. During her stay she was dull and stupid, suffered from moderate, epigastric pain and sensitiveness, nausea and vomiting, and inability to eat solid food. The skin was not hot to the touch. Pulse 80. Her bowels were kept open by laxatives or enemata. There was a trace of albumin in the urine. The abdomen was full and rounded, and nothing abnormal was discovered on palpation. During the latter part of her stay she was able to sit up daily for a short time. She left the home without the knowledge of the physician, walked some distance, and was supposed to have drunk to excess.

Three days later she was seen by Dr. Sears, who found her suffering from severe pain in the right hypochondrium and epigastrium, with marked prostration. Her thirst was intense, but she immediately vomited everything swallowed. There was constant expectoration of thick, frothy mucus. Pulse 120; temperature 99.4° F. The abdomen was distended, the walls rigid. There was especial prominence of the epigastrium and right hypochondrium. This condition persisted during the three following days at the end of which she was taken to the Massachusetts General Hospital, where she died in the course of a few hours, at the end of the seventh week of her illness.

Dr. Whitney, who made the post-mortem examination, found the pancreas of normal size and density, in general of an opaque-gray color.

At the lower part of the head was a trabeculated cavity with dirty green, shreddy walls and containing cheesy, necrotic material. A large branch of the duct, with a ragged edge, opened directly into this cavity. Its wall near the cavity was green and soft. The main duct was intact, but contained near its outlet a small quantity of dirty brown, viscid fluid. The parapancreatic fat-tissue formed a part of the wall of the cavity above mentioned. Near the splenic end of the pancreas was a hole in the fat-tissue as large as a walnut and containing a dirty green fluid. Elsewhere in the neighboring fat-tissue, and in that of the mesentery, meso-colon, and posterior abdominal wall were numerous opaque-white, pap-like nodules from the size of a pinhead to that of a

pea. They were at times aggregated in clumps; the contents could be squeezed out. The smallest nodules were frequently surmounted by an injected border.

There was nothing abnormal in the portal vein or its immediate radicles. The liver was in a condition of brown atrophy, and there were minute, pale yellow calculi in the gall-bladder and common duct. There was no evidence of a general peritonitis, but on cutting through the meso-colon the stomach and colon were found slightly adherent. The microscopic examination of the fat-tissue showed characteristic, necrotic patches with a margin of round-celled infiltration. Also occasional small abscesses and more diffused infiltrations of leucocytes.

In addition, occasional, circumscribed, round spots were seen, composed of more or less elongated and flat cells, enclosed within a fibrous border. The cells varied in size, some being considerably larger than fat cells and containing several nuclei, while the smallest had a diameter four times that of a red blood-corpuscle. These patches suggested a lymph vessel plugged with desquamated and œdematous endothelium.

Dr. H. Jackson, under the supervision of Dr. Ernst, made a bacteriological analysis of the necrotic fat tissue from the above case. From Dr. Ernst's report it appears that four varieties of bacteria were isolated:

1. A liquefying, fluorescent organism, which proved to be a fine, short rod, half the size of the bacillus of tuberculosis.

2. An organism closely resembling the staphylococcus pyogenes citreus, both in the manner of its growth and in its microscopical appearances.

3. Very short, rather thin, non-liquefying rods, which formed thin, grayish, almost translucent and much wrinkled pellicles on the surface of the gelatine and agar-agar, around the mouth of the needle track.

4. The only organism found in large numbers. The cultures grew as finely beaded colonies along the needle track, with a flat, pearl-gray top extending two or three millimetres over the surface of the nutrient material. Microscopic examination showed the organism to be composed of very short, thick rods, resembling somewhat the appearances found in one or two of the sections of the necrotic tissue. It did not liquefy the gelatine.

Of twenty-one patients, seventeen were males and four were females; all were adults, whenever ages were mentioned, and in eighteen cases the age was given as follows:

Years of age.	Number of cases.
From 20–52	3
" 25–30	4
" 30–35	2
" 35–40	2
" 40–45	3
" 45–50	0
" 50–55	1
" 55–60	1
" 60–65	1
" 65–74	1

Previous attacks of indigestion of greater or less frequency and severity were present in about one-fourth of the cases. These attacks were usually regarded as gastric or bilious. One patient suffered from sick-headache, while another was subject to diarrhœa during his drinking bouts. Three were distinctly intemperate, two might be regarded as gluttonous, and one was exposed to hard work and extra hours.

The immediate attack was precipitated in two instances by errors in diet, in the one case a probably putrid sausage having been eaten. The attack was greatly aggravated in a third case by a dinner of roast goose and cabbage. Two weeks of catarrhal symptoms with great debility were the antecedents of another case.

A striking feature in the history of these cases of suppurative pancreatitis is the tendency of this affection to become chronic. Of fourteen cases, six were fatal in the first month, three during the second month, and five at various periods between four and eleven months. Death might take place at the end of the first week and even the more chronic cases often began with distinctly acute symptoms.

It is, therefore, desirable in the consideration of this series of cases to group them with particular reference to the rapidity of their course.

The cases of acute, suppurative pancreatitis usually began suddenly with severe, generally intense gastric, epigastric, or abdominal pain, vomiting, and sometimes great prostration. The vomiting might be incessant and distressing, or it might give temporary relief to the pain. The ejected fluid was sometimes stringy and brown. The bowels were usually constipated, although diarrhœa might occur within the first twenty-four hours. This latter symptom was not infrequent at a later date of the disease.

Fever, usually slight, was the next conspicuous symptom, being manifested about the third day. At the same time the upper abdomen, especially the epigastrium, was likely to become distended, tympanitic, and sensitive. Hiccough, sometimes quite obstinate, was not infrequent at this stage, and occasional chills were to be met with. The abdomen, in general, then became moderately swollen, tense, and tympanitic.

With the violent onset and persistence of these symptoms death might occur, perhaps in the course of a week or more.[1] The pancreas then was markedly enlarged, reddened, and studded with hundreds of small abscesses, many of which had burst into the peritoneum. The associated fibrino-purulent peritonitis was most marked in the upper abdomen. In the second case,[2] where death resulted in eleven days, the attack was apparently recurrent in a corpulent person who had suffered for a year from symptoms which might be attributed to pancreatic disease. There were found in the pancreas numerous small, yellowish-white prominences, alone and in groups, with soft, pap-like contents. They were present on section as well as superficially. The contents were fatty-degenerated cells and detritus. The walls of the smallest cavities were infiltrated with round cells while those of the others were smooth. A group of these prominences were grayish discolored, gangrenous, the superficial peritoneum being perforated and shreddy. Similar nodules were found in the mesentery and in the transverse meso-colon. In the latter was a circumscribed necrosis with floating shreds and fresh, peritonitic adhesions. The pancreas was irregularly traversed by narrow and broad bands and by a diffused development of fat-tissue. Not only does the clinical history of this case suggest a recurrent and finally fatal attack, but the pancreatic lesions also point to a long-standing process. Fibrous bands, fatty-degenerated cells and smooth-walled cavities filled with

[1] Case XLVI. [2] Case XLIX.

detritus favor this view. The description of these nodules suggests that many of them were probably foci of fat-necrosis, with gangrenous sloughing of the superjacent peritoneum.

An acute suppurative pancreatitis, however, very rarely terminates at this early date. The symptoms already described may persist for three or four weeks, with progressive emaciation and debility, and death occur from exhaustion. Under such circumstances the single abscess has been found surrounded with adhesions.

In another series of cases, beginning equally violently, there may be frequent chills and irregular, atypical, often high, fever, the maximum temperature being 105.8°.

Slight jaundice may be associated. The pains extend into the hypochondria and may spread from this point downward.

The liver, perhaps the spleen, may be palpably enlarged—the symptoms are conspicuously those of blood-poisoning, and the patient dies collapsed in the sixth or seventh week. An abscess as large as large as a hen's egg, filled with greenish-yellow pus, may then be found in the pancreas. Also a pyelophlebitis apparently the result of the pancreatic abscess and associated with multiple abscesses in the liver, and acute peritonitis.[1] Death at the end of seven weeks may result from the extension of the pancreatic abscess to the parapancreatic fat-tissue, with the production of multiple nodules of fat-necrosis.[2] In this case the symptoms of epigastric pain, vomiting, constipation, and swelling were interrupted by a period of several weeks of comparative comfort to be followed by marked prostration, incessant vomiting, severe epigastric pain, and fever.

Another event in the history of acute suppurative pancreatitis, found in the course of the third or fourth week, is the tense and swollen, painful, and sensitive upper abdomen which follows the pain, vomiting, constipation, and fever. A diarrhœa then becomes conspicuous, perhaps preceded by violent paroxysms of lancinating pain shooting laterally in the epigastrium, producing temporary collapse.

The loose stools may be thin, yellow, and feculent at the outset and then become profuse and watery. This symptom may then subside, with a lowering of the fever and a general improvement, to recur after a few weeks with fever and abdominal distention, progressive emaciation, and increasing weakness, ending in death in the tenth week.

Several small abscesses have then been found in the enlarged and firm pancreas, with sclerosed peripancreatic tissue. Communicating sinuses unite these abscesses and open into the adherent stomach and duodenum. A splenetic thrombo-phlebitis and a hepatic abscess may be associated, also a fibrinous peritonitis especially marked in the upper abdomen.[3]

The early symptoms may be less severe and the disease be announced by progressing weakness and emaciation. Loss of appetite, slight jaundice, perhaps diarrhœa, may occur. There may be neither fever nor pain, or there may be obscure symptoms of peritonitis.

Finally, anasarca or ascites becomes apparent, and death occurs from exhaustion, perhaps at the end of five months. The pancreas may then contain a diffused abscess, following the course of the ducts and opening into the cavity of the lesser omentum, which was filled with pus, and in its turn emptying into the duodenum through a sinus in the mesentery. these conditions being associated with a fibrino-serous peritonitis. The pancreatic abscess may extend at an earlier date even to the omental cavity, thus forming a great pus-cavity extending as low as the lowermost coils of the ileum, and walled in by adherent intestines and stomach. The greater part of the pancreas may be destroyed. The common duct may open abruptly into the abscess of the pancreas, and leave it at the hepatic end. There may be an associated thrombosis of the portal vein continued into its primary sources, and the pancreatico-duodenal artery may be eroded, with hemorrhage into the cavity of the abscess. A recent peritonitis may be associated, and in one of these somewhat protracted cases with extension to the omental cavity, a bronzed skin was present.

Finally, there are the most chronic cases, which extended over a period of nearly a year. As a rule, no severe pain occurs at the outset, but the patient gradually becomes weak and thin, vomiting may be frequent, and a sense of distention of the stomach after meals or of epigastric pain be complained of. There may be little or no fever, or periods when chills and fever occur. The stools may be consistent, not colored with bile, and very fetid, or later they may be very offensive and mixed with blood. There may be a free communication between the pancreatic abscess and the duodenum, or the latter may break into pultaceous shreds when handled. The entire pancreas may be converted into a trabeculated cavity filled with creamy pus and cheesy masses, or it may be indurated and infiltrated with pus. In one of these protracted cases[1] diabetes appeared after the third month.

Noteworthy in these cases of suppurative pancreatitis is the rarity with which a circumscribed tumor is to be found. A swollen, tympanitic epigastrium is the rule, and very rarely a circumscribed resistant spot was to be felt above the navel, to the left of the median line.

Jaundice occurred in less than one-fourth of the cases. It was then usually slight. Its intensity in one case was connected with abscesses in the liver and dilated bile-ducts.

Another fact of considerable importance is the usually small size of the spleen. The rule was, that no enlargement was noticeable even in those cases in which the thrombotic obstruction of the splenic or portal vein was recorded. The small spleen was usually of normal density.

From the above consideration it is evident that there are cases, few in number, of acute suppurative pancreatitis, which run a course similar to that described in connection with hemorrhagic inflammation. They may begin with equal suddenness, present the same grouping of symptoms, but are not so early fatal. They are more rarely associated with evidences of fat-necrosis, which were present in but two instances.

Although Klebs[2] regarded pancreatic abscesses, not arising from a peripancreatitis or from suppurating cysts, as of doubtful existence, it is apparent that this view is opposed by the evidence here recorded. It is also evident that the extension of an abscess from the neighbor-

[1] Case LIV. [2] Case LV.
[3] Case XL.

[1] Case XLV. [2] P. 21.

ing lymph-glands to the pancreas is of extreme rarity. The only evidence in favor of this view is that offered by Portal,[1] and in the case[2] reported by Smith. The possibility that a pancreatic abscess may be due to inflammation of the appendix is evident from Moore's case,[3] although the connection between the two may have been through a mesenteric thrombo-phlebitis, arterial embolism, or through the coexistence of acute pancreatitis and appendicular inflammation.

The possibility that a pancreatic inflammation may be excited by the passage of a lumbricus into the pancreatic duct is admitted in connection with the appearances in Case XLVIII. It is still more probable, however, that the worm entered the pancreas after the establishment of the inflammation. Its presence there might be merely accidental, even taking place after death, as is likely to have been the fact in Case XL.

(To be continued.)

ORIGINAL ARTICLES.

REPORT OF A CASE OF HYSTERO-EPILEPSY IN A MAN.

BY LEWIS H. ADLER, JR., M.D.,
RESIDENT PHYSICIAN, UNIVERSITY HOSPITAL, PHILADELPHIA.

THE patient, J. J. B., æt. twenty, single, was a tall, muscular fellow, whose intellect, if anything, was a little impaired. He was admitted into the nervous ward of the University Hospital, Oct. 26, 1888, under the care of Professor H. C. Wood.

From his mother the following history was obtained: Was of Irish parentage, born in the United States. Family history uncertain but apparently not important. At the age of seven had diphtheria; otherwise was always healthy up to twelve years of age when he fell down a flight of iron stairs at school and struck his head against the last step. He was sliding down the banisters at the time and slipped and fell from the second-story to the bottom of the building. The fall did not harm him greatly as he was not rendered unconscious, nor did he experience much subsequent pain. Since this accident he has complained, more or less, of a localized tenderness upon pressure being made over the region of head struck.

When thirteen years old he had another severe fall, this time through an open hatchway a distance of ten or fifteen feet. Fell upon his side, but with the exception of some slight bruises he escaped serious injury. Two years later, at the age of fifteen, he became subject to fits. Had never been affected so before. Stated that he was always aware of their oncoming but was not conscious during the attacks. He never falls during these paroxysms, as his knowledge of the arrival of an attack is such that he is enabled to lie down before its onset.

Acknowledges indulging in unnatural abuse of the sexual function, or masturbation, since he was twelve years old. Also states that he has been subject to involuntary seminal emissions, occurring sometimes as often as two or three times during the twenty-four hours. As a result he gradually became depressed and was constantly reminded of the fact that he had ruined himself, as he supposed for life.

His condition upon admission to the hospital was as follows: Physically he was well proportioned and in good general health; mentally and morally he was found deficient. His face was careworn; eyes bloodshot and restless, indicative of his mental excitement. Had used tobacco to excess but under medical advice had stopped it; never indulged in stimulants of any sort.

The frequency of the fits, at this time varied. Sometimes two to three a week; again, he would be free from them for days, but never more than a couple of weeks at a time.

Examination of the viscera was negative. There was slight palpitation of the heart, but not very marked. Firm pressure over the region of the head hurt in the fall, as previously mentioned, caused a cry of pain and provoked considerable emotional excitement, patient saying that unless it was stopped he would have a fit, all the while squirming around and contorting his body as though in great suffering. It was never possible, however, to bring on an attack by this method.

It might be stated here that moral persuasion combined with a sedative medicinal treatment soon brought about a change for the better in the patient's condition, both mentally and morally. The involuntary nocturnal seminal emissions were gradually lessened in number until it now might be said that they are simply physiological.

A description of one of his attacks will suffice to illustrate the rest, and as my notes of his first fit which I witnessed are the fullest account that was recorded, I will give it in detail.

It was fully a week after entrance into hospital that he had one of the paroxysms. Two days previously he complained of a feeling as though a ball was rising up and sticking in his throat, the *globus hystericus* of writers. Soon after this he remarked that an attack was near at hand. This sensation the following day was supplemented by a sort of stupor, associated with a tendency to melancholia, and a noise in head resembling escaping steam, which was most marked upon the right side. The next day about 3 P. M. I was hurriedly sent for, saying that J— was about having a fit. I found him lying in bed. He remarked that his eyes were heavy and misty and that his head felt as though it were expanding and would burst. Soon a twitching of the eyelids was noted; then of the muscles of the face, particularly of the mouth; these were followed by a convulsive tremor which seemed to pass down over the entire body and limbs. Head moved from side to side. Eyes became fixed and staring. He ground his teeth together and some difficulty was experienced in keeping the tongue from being bitten. Respirations became shallow and slow, and at times seemed to stop. A series of convulsive movements next ensued; not, however, of a very marked or active type. These were followed by rigidity of muscles and pronounced opisthotonos—not of the extreme type but sufficient to attract attention. This attack lasted for about a quarter of an hour and ended by his becoming gradually calm and muscles

[1] Loc. cit. [2] No. XLIII [3] No. L.

relaxed. He then sat up in bed and gazed vacantly around. Upon being spoken to, he seemed to understand fully what was said, but his answers were given in a very hesitating way. In about another fifteen minutes from the time the paroxysm started he become quiet and laid down. There was no rise of temperature after the attack. During the spasm he seemed to be unconscious of his surroundings. He remarked afterward that all he could remember of the attack was somebody speaking about the necessity of placing something between his teeth to prevent him biting his tongue, and that he had a queer, confused sound in his head which was probably just before he regained consciousness.

The treatment of this case, directed toward controlling the epileptic seizures, did but little, if any, good; his condition vacillating, sometimes worse, sometimes better. Finally, at the suggestion of Professor Wood, on the 23d of last November, the patient was thoroughly etherized and a circular flap of tissue was cut and dissected up over the region of the tender spot upon the head. The wound thus made was sewed up, dressed antiseptically, and bandaged. He was put to bed and kept there for two weeks. When he recovered from the anæsthetic he was told that the operation had been entirely successful, and that he would not be liable to any more fits; or, if so, they would be very mild in character and would occur at rare intervals.

At end of time, as stated above, he was allowed to get out of bed and put at light work about the ward. At the beginning of this year he was discharged from the house, and up to present writing —two months and a half since the operation—he has had but two slight returns of former attacks. These were brought on by undue excitement incident to participating in atheletic sports. He is now enjoying excellent health, has no seminal emissions, and shows no tendency to have a further return of the old trouble.

Hystero-epilepsy in the male is a rare affection. The diagnosis is based upon the following points of difference between

Hystero-epilepsy (in this case),	and	True idiopathic epilepsy.
1. Attacks never occurred at night.		1. Frequently occur at night (Da Costa).
2. Never ushered in with a cry.		2. Usually the patient screams at the onset of a paroxysm.
3. Was not the result of heredity.		3. Heredity plays an important factor in its etiology. (According to Gower, 35 per cent.; Hamilton, nearly 50 per cent.)
4. Gradual loss of consciousness.		4. Sudden and complete loss of consciousness.
5. Seldom fell; always knew when attack was coming on.		5. Usually fall, and with frequent serious injury resulting.
6. The frequency of attacks showed no influence upon patient's mental or physical condition; the trouble previously alluded to in this respect being attributed to the results of self-abuse; a fact later fully demonstrated by the result of treatment directed to this trouble.		6. The number of attacks have a decided effect on the mental condition (Mills).
7. Patient was of good physique and well nourished.		7. The reverse of this is true
8. Only slight distortion of countenance.		8. Distortion of face and eyes usually very great.
9. Pupils reacted to light.		9. Generally the pupils are insensible to light.
10. Convulsions were clonic, as a rule, and equally distributed over entire body.		10. Convulsions often more marked on one side than on the other, and more tonic than clonic; usually, however, the spasms are universal (Wood).
11. Paroxysms were not usually followed by sleep or any perceptible impairment of intellect.		11. It is the exception when attacks are not followed by profound sleep, by headache, and dulness of intellect.

The prognosis here seems to be favorable. The sham operation through which he went, and which effected so decided an influence upon his condition, through the mental impression which it made, will possibly result in a cure.

A somewhat similar case, of a woman, is reported in the *Lancet*,[1] under the title of "Castration in Hysteria," in an hysterical patient who had suffered for years from obstinate vomiting and severe ovarian pains. She became very weak, and finally consented to oöphorectomy as the only hope. The operation —performed under an anæsthetic—was a mockery, the skin only being incised; she was, however, perfectly cured.

At the meeting of the American Neurological Association (June, 1884), in the discussion which followed the reading of a paper by G. L. Walton,[2] Spitzka, of New York, cited a case of Israel's, of Breslau, in which a patient was cured of hystero-epilepsy by a sham operation—a superficial incision in the parietes of the abdomen.[3]

It is true that cases supposed to be cured often relapse, but it is hoped that such will not be the result in this incident. The general improvement, both in regard to his sexual organs as well as his mental state, is against a return of the disease. So is the sudden cessation of the attacks, which previously to the operation occurred several times weekly. Likewise, the fact that we have a male to deal with instead of a woman is additionally favorable.

ON UNUSUAL METHODS OF ACQUIRING SYPHILIS, WITH REPORTS OF CASES.

By L. DUNCAN BULKLEY, A.M., M.D.,
of New York.

(Concluded from page 236.)

II. Syphilis Brephotrophica.

Two great divisions are met within this group, relative to: 1, the nutrition of infants; and, 2, attendance upon them. Literature is very full of data

[1] Lancet, vol. ii. p. 588.

[2] A Contribution to the Study of Hysteria as Bearing on the Question of Oöphorectomy.

[3] Mills: Hystero-epilepsy (Pepper's System of Medicine, vol. v. p. 312).

bearing upon this branch of the subject, and many of the points connected with it are so familiar that they need only be mentioned. Happily, this mode of communicating syphilis is becoming more rare as its dangers are more recognized, and it could hardly be possible now to have such epidemics of syphilis from this source as have been reported in earlier times. Thus, in a little town in the southeast of France the celebrated "Pian de Nerac" occurred, in which more than forty women and children were infected with syphilis before the nature of the trouble was recognized, it all starting from a single syphilitic child.

But isolated cases are still constantly occurring, and among my sixty-six cases of extra-genital chancres are found six instances of chancre of the breast, and there were also at least four children known to have been infected from them. The following case illustrates the fact that infection may sometimes take place even when the nature of the disease is known, and greater or less precautions are exercised against infection.

CASE VIII.—Mrs. X. M., a very intelligent patient, was obliged by the sudden death of her husband to take a strange child to nurse, when her own was but a few months old. Fearing contamination, she very carefully kept the strange child on one breast, while she sedulously gave the other alone to her own child. Within some weeks the foundling died, with fully developed hereditary syphilis, and the mother then gave both breasts to her own child. In the course of some weeks later the breast which had nourished the strange child became sore on the nipple, and the ulcer resisted treatment for a long time, so that after awhile her own child ceased to nurse from it, and was kept on the other breast alone. In the course of time the mother became affected with general symptoms, and applied for treatment with a well-marked papulo-tubercular syphiloderm. Her child soon developed syphilis also, but it was never learned where the poison entered. It is more than probable that the lesion was in the mouth and gave very little trouble, as is commonly the case in infants who acquire syphilis at the breast. The child, however, suffered severely from constitutional syphilis, and was under my care through a number of years, and had considerable bone disease.

Syphilis has frequently been communicated also by means of the hand-feeding of infants, and cases are on record where feeding-bottles, sugar-teats, spoons, cups, etc., have been the means of conveying the poison, which need not be dwelt on at present.

The ordinary care of infants also affords a frequent opportunity for the interchange of syphilis between them and their attendants, in both directions. Various articles used in the nursery toilet have been reported as conveying syphilis, such as sponges, syringes, combs, napkins, etc.; and one infant acquired the disease from contact in a cradle with the lining which had become saturated with the secretions of a syphilitic child. Scratches and tooth wounds given by infants have also been known to communicate syphilis to attendants, while they in turn have not infrequently infected healthy children by fondling, by means of extra-genital chancres in various locations. A number of cases are on record where attendants have acquired a chancre in the site where a syphilitic infant had rested in carrying; in one instance, reported by Waller, the attendant was seventy years of age.

III. SYPHILIS TECHNICA.

This third main class of *syphilis insontium* embraces a large number of sub-groups, with a variety of individual methods of transmission of syphilis, in connection with the various forms of body service, medical and surgical, as also by nurses and attendants on those affected.

We find here three very distinct main divisions, according as, 1, when the operator is the victim; 2, when the operator is the syphilifer; and 3, when the operator is the medium.

1. *When the operator is the victim.* Physicians and others in the pursuit of their profession have, as is well known, acquired syphilis in almost numberless instances, and in the most unsuspected manner, and it is hardly necessary more than to allude to the subject.

Cases are on record where the poison has been received by surgeons during operations, and also by anatomists during dissection; it is also not infrequently acquired during manipulative proceedings, and students and others at venereal clinics have contracted chancres on the fingers and elsewhere in the careless handling of syphilitic sores. Jullien[1] relates a case where an eminent specialist who had a slight bleeding wound on the finger was called upon to examine a chancre on the upper surface of the glans penis. He held the wounded finger carefully aloof from the sore, but during the examination he found that there was a second chancre of the scrotum which had just come in contact with the finger which he had striven to protect. Realizing the danger he at once washed carefully and thoroughly cleansed the part, but all in vain, as a chancre formed on the wounded finger and the syphilis ran its course. Dentists have also been reported to be infected in practising their profession.

The largest numbers of syphilitic inoculations in this group are furnished by accoucheurs and midwives, and very many instances of this nature are recorded in literature.

[1] Jullien, Traité pratique des mal. ven., 2d ed, Paris, 1886, p. 537.

In the list of extra-genital-chancres already given, there are found seven cases of chancre of the finger, five of which occurred in physicians. The following case is of peculiar interest, inasmuch as the sufferer also infected his wife, although he had exercised as he thought, the utmost caution against such a misfortune.

CASE IX.—Dr. X. C., aged thirty-one, first noticed a soreness about the base of the nail of the third finger of the left hand during the latter part of June, 1884; this increased in severity until a chancre of some size developed, which remained, though partially healed, at the time of his visit in September of the same year. He had had only local applications, including burning with nitrate of silver.

Ten days before his visit a slight eruption had appeared upon the forehead, which increased, so that when he presented himself most of the body was covered with a characteristic maculo-papular syphilide; there was also malaise, with aching in the limbs which he had considered malarial and had treated with quinine. There were also very general adenopathy and soreness of the throat just beginning, and later he had a severe iritis and other symptoms of constitutional syphilis. When first seen the entire end of the finger was thickened and red, the nail raised from its bed, and at its root an ulcer was seen circular in shape, presenting an almost healed, purplish, glazed appearance. The infection was traced to a confinement case about a month previous to the appearance of the sore, when a hydrocephalic child was delivered dead born of a mother whom he believed to be syphilitic.

Almost six months after the first visit of Dr. X. C., he brought his wife to me with a fading maculo-papular syphilide, presenting very characteristic lesions about the mouth and chin, with mucous patches abundant in the throat, and general adenopathy. The history was that nearly two months after her husband's first visit she had begun to feel poorly, with malaise and bone-ache, until about a month later she took to the bed, with what was suspected to be typhoid fever by several physicians who saw her. A slight eruption had appeared on the abdomen and chest, which was regarded as an usual form of the typhoid exanthem. A month after the time that she took to bed the throat began to be sore, and soon the glands in the neck became enlarged.

No clew could be found as to the method by which she received the poison; she had no initial lesion on any external part of the body or buccal region, nor could any trace of a primary sore be found in the genital region or vagina, even by a well-known gynecologist, who examined deeply for it. The case might possibly lend weight to the supposed communication of syphilis by the seminal fluid, and her husband, who had studied the case carefully, suggested that infection might have occurred through a pregnancy, as it was thought that she possibly might have had a miscarriage very early in conception, as there was at the time a delay in her menses, but of this they could not be certain.

In one of the instances of chancre of the finger in the list, the infection occurred on the third finger of the right hand in a lady who had taken all the care of a relative who had an ulcerative disease about the eye, changing the dressings, etc., during six or seven months; during this period the finger became sore at the root of the nail, and as the ulcer healed she had a general eruption, with malaise, bone-aching, etc., followed also by later manifestations of constitutional syphilis.

Physicians and attendants upon syphilitics have also received the infection in other regions than the fingers, and cases are on record where chancres have thus occurred on the eyelids, nostrils, and lips, from conveying the poison on soiled fingers or otherwise, and more than one instance has been reported where the patient has projected the virus by coughing in the face of the physician, and chancre of the eyelid or elsewhere has resulted. One case is on record where a physician acquired a chancre of the tonsil by practising artificial respiration with the mouth on a syphilitic child. Many instances can be found where individuals have become infected by sucking recent wounds, and also by breast-drawing with the mouth.

2. *When the operator is the syphilifer.* In this instance the operator having syphilis communicates his own disease to another by means of some body service. The number of reported cases falling under this category is very large, and come under a variety of heads. We have already seen that accoucheurs and midwifes often contract syphilis in their calling; and, on the other hand, numerous instances are on record where they have been the means of spreading the disease to others, and even in large numbers. The celebrated epidemic of St. Euphemie in France was of this nature. A midwife acquired a chancre on the right index finger, followed by a full attack of constitutional syphilis. She contiuued her calling for four months and communicated syphilis to more than fifty women, and through them at least thirty others were infected. In another epidemic in France over one hundred were thus infected with syphilis, and very recently Klein has reported an epidemic in England in which thirty married women, nine husbands, and two infants contracted syphilis, directly or indirectly, from a diseased midwife.

The operation of breast-drawing by the mouth has also in times past proved a very fruitful opportunity for the intercommunication of syphilis; we have already mentioned the acquiring of syphilis by the operator in this manner, and there are abundant instances on record where the disease has by this means been conveyed to numbers of innocent victims. As early as 1654 an event of this nature was reported, where a professional breast-drawer infected

many nursing women with chancre of the breast, and these in turn gave syphilis to their nurslings, who again communicated it to others. Although this practice is less common in this country and among the more highly civilized people than among the peasantry of European countries, yet cases of this nature still occur here and there, and at times breast-drawing by the mouth has given rise to epidemics of syphilis of considerable size. Leloir[1] has reported an epidemic of this nature occurring as late as 1880, where a woman acquired a chancre of the lip and she infected four women on the breast, who in turn gave syphilis to three nursing infants, one of whom, as also one of the women, died of the disease; one of these infants infected its father through the nursing bottle, and another infant gave the disease to its wet-nurse, who again transmitted it to her own infant.

Among the more curious and unexpected methods of communicating syphilis innocently may be mentioned the practice, sometimes followed, of removing foreign bodies from the eye by means of the tip of the tongue. In two small villages in Russia, Tepljaschin[2] found, among a population of 532 persons, no less than sixty-eight individuals, twenty-three males and forty-five females, who were affected with syphilis, about one-quarter of them being under ten years of age. One-half the entire number had been infected directly by a female quack, who had followed the industry of removing foreign bodies from the eye, and treating trachoma, with the tongue. The woman had herself received the disease in her calling and had continued to spread the same. A number of single instances of the same method have been recorded, and of these at least two[3] have been reported in this country.

Syphilis has also been communicated by means of the sucking of recent wounds, as we have also seen that it may be acquired by the operator in this manner.

Tattooing is now well recognized as one of the avenues through which the syphilitic virus may be accidentally introduced, and a total of no less than seventy-five cases of this nature have been found, reported by a number of different observers. As is well known, the poison is commonly, if not always, supplied from mucous lesions in the mouth of the operator, by means of the saliva used to moisten the needles or ink during the operation.

Among the personal cases of extra-genital chancre before alluded to, there was one where the disease was undoubtedly received in this manner through a tattoo on the right forearm.

[3] Cited by de Beck, Hard Chancres of the Eyelid and Conjunctiva, Cincinnati, 1888, p. 48.

3. *When the operator is the medium.* Our last group of cases comprises those where the operator serves as the medium to convey syphilis from one person to another, by means of various forms of body service. A large number of instances are on record where this has happened, and many of the facts are well known to all and need but to be mentioned.

Vaccination is, perhaps, one of the most widely recognized instances coming under this class, the first authentic cases being reported by Marcolini as occurring in Lombardy in 1814, in which out of forty subjects vaccinated from a child with inherited syphilis almost all were infected. Hundreds of cases have been reported since that date, many of these occurring in epidemics of some size; thus, at Schleimitz and St. Vait in Styria, Kocevar reported an infection of sixty-six persons, of whom thirty-one were vaccinees, from whom nineteen mothers, and eleven others, including children, received syphilis. The epidemic at Rivalta, Italy, is a well-known instance of this mode of infection.

Ritual circumcision has also furnished numbers of victims of syphilis, who commonly receive the infection by the practice of staunching the blood by the mouth of the operator. The first reported cases of this occurred in 1805, since which time many observers have reported cases, and on one occasion, referred to by Jaffe,[1] thirty boys were inoculated by one operator in Vienna.

Injuries made by dental instruments have been reported by several observers to be followed by syphilis at the site of injury; in these instances, the supposition is generally that the poison had been conveyed by the instrument which had received it from mucous lesions or blood from the mouth of a syphilitic person, it not always having been sufficiently cleansed. Roddick[2] reports a case where a chancre formed at the site of extraction of a tooth, the gum being considerably lacerated in the operation.

The following very interesting case illustrates the inoculation of syphilis following a wound by a dental instrument in the tongue.

CASE X.—Mr. X. W., a gentleman of intelligence and position, aged sixty years, came to my office on account of a sore on the tongue which he feared to be a cancer. The history was that, ten weeks before his visit, he had first noticed a little point of soreness on the tongue, which had gradually increased in size, in spite of treatment at the hands of another physician, who had evidently not recognized its character, until latterly it had come to give him so much annoyance that he was conscious of its presence at all times.

[1] Jaffe: Die rituelle Circumcision, etc., Leipzig, 1886.

[2] Roddick: Montreal Medical Journal, vol. xvii. No. 2, 1888, p. 93.

On examination there was found on the right side of the tongue, about an inch from the tip, a hard, inflamed mass, nearly half an inch in diameter, ulcerated in the centre, and with the edges somewhat everted; it was not ordinarily painful, except when irritating food or drink touched it; there was already a small, enlarged and painful gland beneath the jaw on that side. Thinking that possibly the lesion might be due to local irritating causes, he was given a soothing mouth-wash, and an alkali internally. Five days later there was a marked improvement; he had had some roughened teeth smoothed off and had left out his set of artificial teeth. The ulcer then looked less irritated, but its margin was more clearly defined, and the edge harder, the submaxillary glands of that side were more swollen and hard.

The diagnosis of chancre of the tongue was then recorded, and he was placed upon anti-syphilitic treatment, under which the sore rapidly improved; some days later a general maculo-papular eruption appeared, affecting even the palms, with other signs of constitutional syphilis. The ulcer healed rapidly and in six weeks there was only a scar with slight hardness at its base.

In searching for the mode by which the syphilitic poison gained entrance, it was learned that during the month or so previous to the occurrence of the tongue chancre he had been, through the persuasion of a friend, under the care of a dentist of a cheaper advertising order, who, he had noticed, was not at all cleanly in his person or instruments. He could not determine accurately the date of particular injury of the tongue, but work had been done in that portion of the mouth, and he remembered having the instrument slip occasionally. The patient was a married man, with a family, and had certainly not been exposed in any other manner; he was repeatedly questioned on this point, and was himself anxious to learn how he had acquired the disease.

The probability is very strong, therefore, that the poison was conveyed on the dental instrument from some preceding patient who had active syphilitic lesions in the mouth. The likelihood of such exposure and contamination of dental instruments in the hands of those who are careless as to cleanliness is very great, and is illustrated by the fact that this very patient, while under my observation and before the nature of the ulcer on the tongue was determined, and while it was secreting freely, had himself been to another dentist and had had the teeth adjoining the ulcer filed and polished. Too great care can hardly be exercised in warning patients with active mouth lesions of syphilis, or indeed all those in the early, infection period of the disease, against exposing others in this manner.

In earlier times, and especially in rustic communities, the operation of wet-cupping has on repeated occasions given rise to syphilitic contagion, and a number of epidemics of this nature are on record; the earliest of these is the celebrated "Maladie de Brunn" in Moravia, in 1578, where no less than eighty persons were infected in three months by this means, in addition to about one hundred in the surrounding country. In Finland repeated epidermis have occurred from this cause, and in one instance nearly two hundred persons were infected.

Minor surgical operations, such as opening abscesses, scarifying a hydrocele, the use of serrefines after circumcision, and also skin-grafting, have all given rise to chancres at the site of the wound, followed by constitutional syphilis.

Razor wounds also, have not infrequently afforded an opportunity for the entrance of the syphilitic poison, the inoculation occurring possibly during shaving, possibly afterward from other sources.

Among the personal cases of extra-genital chancre already referred to, occur three striking cases illustrative of this mode of infection, and a fourth one, not quite so certain. One of these, which is of special interest from the intense severity of the subsequent syphilis, will suffice to illustrate the subject.

Case XI.—Mr. XX., a druggist, aged thirty-three years, unmarried, came to my office in 1882, on account of a general eruption of a papulo-squamous character, covering almost the entire body and extremities. Although he had been exposed he had never contracted any venereal disease, and at the time of his visit there was no trace of a chancre on the penis or elsewhere, except as to be mentioned.

Upon the left cheek, however, there was a sore which at once attracted attention, and which proved to be a chancre, with the following history:

He had always been shaved at barber-shops, by different persons, using the public brushes and cups indiscriminately. About two and a half months before his visit his cheek had been cut by a new barber, who, he noticed, was uncleanly in his person and habits, and who shortly left the employ. A pimple soon formed on the site of the injury, which was again cut from time to time by the razor, and the place covered with court plaster; the sore enlarged, and later the crust was allowed to remain upon it. Some weeks later he had a chill, followed by pains in the bones, for which he took quinine; the submaxillary glands of that side began shortly to swell, and a little later the general eruption appeared, with which he presented himself.

When first seen there was on the left cheek, not far from the angle of the mouth, and about an inch from the angle of the jaw, an ulcerated surface, circular in shape, and about three-quarters of an inch in diameter, slightly raised, and with a raw, succulent surface, in which many hairs still stood, partly covered with a crust; the lymphatic glands beneath the jaw, on the left side, were as large as small almonds, and some smaller ones were felt in front of the neck. The entire body, head, and limbs were covered with a brownish-red, papulo-squamous syphilide of very characteristic appearance; the throat was very sore from abundant mucous patches.

The subsequent course of the disease was very distressing; the cutaneous lesions were very severe and prolonged; he had an intense choroiditis, and

at times active nervous symptoms, having once also a perfect locomotor ataxia; this latter yielded, as did other syphilitic phenomena, to active treatment, but for over two years, while under observation, he had as severe symptoms of syphilis as are often seen, rendering him helpless on several occasions. Six months after his first visit—that is, nine months after infection—it was recorded that the glands beneath the jaw were still swollen, and the mark of the chancre was still plainly visible on the left cheek.

Surgical sounds and specula are credited with having produced syphilitic inoculation, and in one particular instance, namely, Eustachian catheterization, this has been the source of repeated infection. No less than twenty-five different persons have reported one or more cases of this nature, and of these cases, about sixty were traced to the practice of a certain ear specialist in Paris. Some instances of this mode of infection have also been reported in this country.

Time does not permit of the further elaboration of this most interesting and important subject of the acquiring of syphilis by means other than venereal. But from this hasty, and by no means complete sketch of some of the recorded methods and instances of the communication of syphilis in the various walks and occupations of life, as also from the illustrations given, it is seen that the disease by no means deserves to be classed always as a venereal affection, nor are the sufferers from it always to be looked upon as guilty of sexual transgressions; syphilis occupies an important place, not only pathologically, in the great mass of diseases affecting the human race, but also practically as one which may at any time affect the most innocent and the least suspecting.

Syphilis has been found to attack the young and old alike, irrespective of age or condition, and in all the many instances or classes alluded to, quite independently of any venereal act or possibility. As each new case or series of cases comes to light, it becomes more and more probable that the number of instances in which syphilitic infection has thus innocently occurred is much greater than is commonly imagined. The total number of innocent victims actually mentioned in connection with about one hundred and fifty epidemics, large and small, of *syphilis insontium*, amounts to some thousands, while thousands of separate cases of extra-genital chancre are also found scattered through literature.

When we consider the immense numbers of syphilitic patients seen every year in the public clinics of the world, most of them living without any restraint upon their actions, even during the most contagious period of the disease, it can readily be understood that the liability for others to contract the disease innocently is by no means slight. With a poison so freely secreted from mucous lesions, and so virulent, and capable of being transported and introduced in so many different ways, and, as far as is known, endowed with the possibility of being preserved for an indefinite period, the only wonder is that cases of non-venereal communication of syphilis are not even more frequent than they are now known to be.

The subject of the prevention of syphilis is, therefore, surely one which calls for serious attention, and one which claims the best thought, both of the profession and of the community.

4 EAST THIRTY-SEVENTH ST., NEW YORK.

MEDICAL PROGRESS.

Treatment of Scabies.—DR. JAMES C. WHITE, of Boston, in a paper recently read before the Boston Society for Medical Improvement, advocates the following method of treatment which he states is applicable in every case, however extensive or severe the accompanying inflammatory processes may be. He prefers a mixture of the three active agents and combines them in this way:

℞.—Sulph. flor.	. . . . .	℥ij.
β-naphthol	. . . . .	℥j.
Balsam of Peru Vaseline	. . .	āā ℥j.—M.

This quantity is generally sufficient for a single case. The patient is directed to rub a third of this mixture into the whole surface of the body, from the neck downward at bedtime. He is especially told to rub it between the fingers and upon the penis, and that it must be applied to the back by some other person. He is to sleep in old garments, that the bedclothes may not be soiled. In the morning the skin is to be thoroughly washed with soap and water. The use of the bath in this class of patients is of course out of the question, nor is it essential. The ointment is to be used in this way for three consecutive nights. Generally the itching ceases almost wholly on the first application. The patient is also told not to use it after the third night, unless, after waiting two more nights, there should be a decided return of the pruritus here or there, in which case the salve is to be rubbed into such parts only, and only for two nights running. For very young children he omits the naphthol in prescribing the ointment, on account of its occasional irritating properties.

In cases where the accompanying eczema is severe, it is well to require an inspection of the patient again on the sixth or seventh day, when it will sometimes be found necessary to direct a course of treatment addressed to this residuary condition. A very frequent mistake on the part of the physician or patient at this stage is the conclusion that the appearances, or accompanying itching, are signs of the continued activity of the original affection, and the consequent renewal of the use of the stimulating parasiticide, which only aggravates the existing process. He has often seen cases of post-scabietic eczema in dispensary and private practice, which have been kept going for months by such errors of judgment. It must also be remembered that in prolonged cases of itch the cutaneous nerves have acquired, as it were, the habit of demanding to be scratched, and seem to require

it for a long time after every visible sign of the disease has disappeared, and these cases of surviving pruritus are often mistaken for remaining evidence of the original affection, and mistreated accordingly.

Directions are always given that on the first night of the treatment all the clothes which have been worn next the skin—shirts, drawers, and socks, and the sheets and pillowcases last slept in—shall be thoroughly boiled before being used again. Gloves should be baked or destroyed.—*Boston Medical and Surgical Journal*, February 14, 1889.

Thymol in the Treatment of Diabetes.—DR. BUFALINI (*Annuale Universali di Med. and Rev. Soc. Med.*, No. 31, 1888) states that thymol, which by some has been highly praised as a remedial agent for diabetes, while others claim that it is dangerous, has, in his hands, exerted absolutely no influence on the course of glycosuria and diabetes. Only in two cases of acetonemic diabetes did he obtain, during, as well as shortly after, the administration of thymol, an amelioration in the acetonemic phenomena, namely diminution of the odor of the breath, of the quantity of acetone in the urine, and a general improvement in the patient's condition.—*Journal de Méd. de Paris*, February 3, 1889.

Creolin Pills.—

Make 200 pills.

Sig.—Take two pills, two or three times daily, in decomposition of the intestinal contents, especially during infectious diseases.—*Berliner klin. Wochenschrift*, February 4, 1889.

A Case of Reinfection with Syphilis.—The case is recorded in the *Giornale delle Mal. Ven.*, of a woman aged forty-six, who had contracted syphilis when a child from a schoolfellow. She suffered very severely at the time, and had the characteristic eruptions, tibial pains, sore throat, and subsequent abortions. Ten years later she had well-marked tertiary manifestations, which gained for her the soubriquet of *fistolosa*, in her village. While she was still in the same deplorable condition she was reinfected by her husband, who had a chancre on the penis and was covered with a roseolar eruption. She came to the hospital, and was found to have a typical indurated chancre on the labium, with corresponding glandular enlargement, and a confluent rose-colored papular eruption all over the body. She also complained of general malaise and pain in the shoulders and knees. These symptoms promptly yielded to treatment, and there would not seem to be any reason to doubt the accuracy of the diagnosis in both instances. Indeed, that exceptions should exist in the protection afforded by a prior attack of syphilis, is only what a study of other specific diseases would lead one to expect.—*Medical Press*, Feb. 6, 1889.

The Microbe of Diphtheria.—M. ROUX, sub-director of the laboratory at the Pasteur Institute, in conjunction with M. Versin, has succeeded in isolating the generating microbe of diphtheria. They have studied the conditions in which this microbe is developed; and have succeeded in reproducing diphtheritic infection in rabbits, pigeons, fowls, and guinea-pigs. Pushing their experiments further, they have also isolated the poison secreted by the microbe from which are derived all the asphyxic and paralytic symptoms of croup or diphtheria; and it is foreseen that the time is not far distant when prophylaxis by means of inoculation will be established. This discovery will certainly be a great boon, since diphtheria is one of the most cruel maladies which afflict humanity. In the note on this subject by M. Roux, the author further states that all the experiments on animals tend to prove that the microbe of diphtheria develops only on mucous membranes already diseased, and it is probable that this is most frequently the case in man. Hence diphtheria is particularly frequent after an attack of measles and scarlet fever. Hence also a simple sore throat occurring in these maladies should never be neglected; frequent washings of the mouth and throat of children affected with these two diseases, should be practised with solutions of carbolic acid. Even in confirmed diphtheria, carbolic acid seems to be the most efficacious antiseptic. —*Lancet*, February 9, 1889.

The Local Treatment of Laryngeal Phthisis.—DR. A. SOKOLOWSKI, of Warsaw, concludes an exhaustive article on the treatment of laryngeal phthisis, with the following summary:

1. A cure of laryngeal phthisis, though seldom effected, is possible.

2. Cicatrization of each ulcer which takes place by itself, or through local application, is closely related to the general condition and the character of the local changes in the lungs.

3. The best local results are obtained from the combined treatment by lactic acid, surgical procedures, and the galvano-cautery.

4. General treatment should go hand in hand with the local treatment.—*Wiener klin. Wochenschrift*, January 31, 1889.

Salicylate of Cresol.—At a meeting of the Academy of Sciences PROF. BOUCHARD read a note for Dr. Letzinski, of Berne, on the salicylate of cresol, which is not soluble, and which is a powerful antiseptic. This medicament has, according to the author, given good results in acute rheumatism. As it is possible to saturate the intestines without inconvenience, and as the microbe of cholera appears to have its principal habitat in the intestines, Dr. Letzinski thinks that this substance may be employed with success in the prodromic period of the choleraic attack. M. Bouchard, however, makes some reserve on this last point, for he does not participate in the opinion of those who hope to cure cholera with antiseptics introduced into the intestines.—*Lancet*, February 9, 1889.

Nature and Treatment of Diabetic Coma.—DR. STADELMANN, of Dorpat, in a recent article in the *St. Petersburgische Wochenschrift*, points out the great similarity which seems to exist between the coma of diabetes and the condition produced in herbivorous animals by inducing acid intoxication. Amongst other points, he refers to some analyses by Minkowski, of the gaseous contents of the blood. In the normal condition, the blood of the

rabbit contains 25 per cent. of carbonic acid; but when the animal is suffering from artificially induced acid intoxication, the carbonic acid is diminished. Thus, in one instance, Minkowski found it 16.4 per cent. with a moderate degree of intoxication; when the latter was increased, the percentage of carbonic acid fell further, first to 8.8, and finally to 2.9 per cent. In order to compare this with the gaseous changes in the blood of diabetics, he examined the blood of a patient before and during coma, the carbonic acid being respectively 17 and 3.34 per cent. In order to ascertain whether this diminution of the carbonic acid in the blood was merely due to coma as such without reference to its cause, he examined the blood of a comatose patient, not a diabetic, whose condition was due to meningitis. Here the carbonic acid amounted to 28.2 per cent. The acid existing in diabetes appears to be oxybutyric acid, which in some cases appears in the urine to the extent of something like three ounces per diem. Some years ago Dr. Stadelmann found a new acid, which he believed to be crotonic acid, in considerable quantity in certain cases. He now, however, considers it merely a substitution-product from oxybutyric acid.

The indications for treatment supplied by these views are, of course, to combat the acid by large quantities of alkali. Several attempts have been made to treat diabetic coma by injecting into the veins from one to four ounces of carbonate of soda dissolved in about four pints of water, with a little chloride of sodium. In only one instance, however, has this proved successful, and unless it is done very early no good result can be fairly expected of it. It is found that the urine in twelve hours after the injection is intensely acid. Better results are to be obtained in attempting to ward off coma by giving alkalies freely. Thus, Dr. Stadelmann prescribes about an ounce of tartrate or citrate of soda dissolved in about half a pint of soda-water two or three times a day, and has found great reason to be satisfied with this line of treatment. Of course, if coma should come on, he would have recourse to alkaline intravenous injections without loss of time.—*Lancet*, Feb. 9, 1889.

Treatment of Minute Nodules of Lupus.—DR. UNNA (*Monatshefte für prakt. Dermatology*, No. 19, 1888) bores out each nodule, after the mass of deposit has been got rid of, with a 10 per cent. sublimate point, then dresses the part till healed, with the following ointment suggested by Dr. Brooks:

R.—Salicylic acid	20 parts.
Creasote	40 "
Simple ointment	40 "

—*Edinburgh Med. Journal*, Feb. 1889.

Action of Sulphonal.—DR. RUSCHEWEYH-JEUA reports in the *Neurologischen Centralblatt*, No. 21, 1888, the following results obtained with sulphonal: of 212 administrations given at the psychiatric clinic its action proved fruitless in only twenty-four, or 11 per cent. Until recourse was had to Dr. Kast's latest method of administration (mixing the drug with one pint of milk or hot bouillon and taking it at supper time) the results were still less favorable. The mixture thus being rendered intensely bitter, one can, should the same hinder digestion, add to it a few drops of hydrochloric acid. If the hypnotic was prompt in its action, the consequent lassitude generally observed on the following day was not noticeable and yet in most cases sleep was obtained the following evening without any of the drug having been taken. The author explains this circumstance by the fact that sulphonal circulates in the blood for twenty-four hours and is thus enabled to still exert its physiological action the second evening. Only in the very excited paralytics was daily administration necessary. Excellent results were obtained from its administration in the case of a morphine-eater, a female, as well as of two syphilitics who suffered from insomnia caused by the pain consequent on calomel injections.—*Deutsche med. Wochenschrift*, Jan. 31, 1889.

Artificial Maturation of Cataract.—DR. PARISOTTI, of Rome, in a lecture published in the *Riforma Medica*, describes two cases in which success appeared to follow attempts to induce artificial maturation of cataract by a procedure differing somewhat from the operations proposed by other ophthalmologists for this purpose. Having produced local anæsthesia by means of cocaine, and having washed the eye with an antiseptic solution containing corrosive sublimate, Dr. Parisotti makes an incision in the upper part of the sclero-corneal border, about six millimetres in length; the pupil is then dilated by atropine, and, the aqueous humor having been let out, rather energetic massage is applied to the cornea for about a minute. The antiseptic lotion is again applied, and a bandage kept on for three days. In two or three weeks considerable progress is to be observed in the maturation.—*Lancet*, February 9, 1889.

Salol in Cholera.—DR. W. LOEWENTHAL, at a meeting of the Académie des Sciences, stated that he had conducted a number of micro-biological experiments, the results of which led him to conclude that the bacillus of cholera only develops toxic properties when it comes in contact with the pancreatic secretion. Guided by this he searched for a drug, which would be harmless to the human economy and still prevent the development of the cholera bacillus in the pancreatic fluid. Salol he believes to have this power, since, in the presence of fresh pancreatic fluid, it destroys cultures of cholera bacillus and if first mixed with the culture material (generally gelatine) renders this material sterile.

To prove that the drug itself was perfectly harmless, the author himself took at ten o'clock one morning seventy-five grains, and the same evening at seven o'clock, seventy-five grains more. The morning dose, which he took fasting, produced no ill effect save a passing vertigo, while the evening dose prodnced no symptoms whatsoever. The urine became somewhat darker and remained so for forty-eight hours from the time of the ingestion of the second dose.

Until further clinical investigations have shed more light on the matter, the author proposes that this drug should be used as follows:

As a prophylactic: three times daily after the principal meals, thirty grains each time.

As a therapeutic agent: sixty grains to be taken when the first symptom of cholera shows itself and then fifteen grains every hour.

As much as five drachms may be administered daily. —*Revue de Thérapeutique*, Feb. 1, 1889.

Diabetes and Tumors.—DR. TUFFIER has recently published a monograph on this somewhat important subject in the *Archives Générales de Médecine*. The coincidence of diabetes and neoplasms, only noted hitherto in a few scattered publications, and entirely overlooked in standard text-books, does not appear to be rare. This coincidence is not surprising to the author. He accepts M. Verneuil's bold theory that both tumors and diabetes are related to the arthritic diathesis. Already almost every form of tumor has been observed in diabetic patients. Almost every form of diabetes has been found to attack persons already the subjects of tumor. As a rule, the constitutional disease comes first; the patient is diabetic already before the tumor makes its appearance. Malignant tumors, as a rule, advance without causing much pain, and somewhat slowly in these cases, but they proceed more rapidly than the diabetic symptoms. They are apt to be taken for innocent growths. The complication in question is very serious in respect to operative interference, as we all know. No surgeon should think of removing small, innocent tumors which are causing no trouble.

Dr. Tuffier describes two instructive cases. In the first, death occurred forty hours after the removal of a small parotid tumor. The fact that the patient was diabetic had been overlooked. This was also the case in the second example of the dangers of operation under the circumstances. "A little hypertrophic tumor of the skin of the cheek" was removed at the patient's request. Phlegmonous erysipelas, followed by sloughing, set in and killed the patient within five days. Urgent operations must, Dr. Tuffier asserts, be undertaken with great caution. The safer are preferable to the most thorough, in his opinion. When an operation appears absolutely necessary, but not urgent, it is important to spend some time in reducing the diabetic symptoms by medical treatment. Should, however, all the sugar and polyuria disappear, the surgeon must still never overlook the nature of the patient's diathesis. Under the most favorable circumstances, in any case of that kind, deep operations and prolonged dissections, free division of vessels, and the formation of large flaps are to be avoided. The slow progress of tumors and the little pain which they produce are important facts, according to Dr. Tuffier. He has found that malignant tumors lie almost latent in diabetic subjects for a long period. Removal of a similar growth from a healthy subject would hardly insure him against so long an interval of time before recurrence. When an operation is thought advisable, the thermo-cautery is preferable to the knife. No attempt to insure union by first intention should be made if it involves the slightest traction on skin-flaps. The wound must be laid open, but dressed with extreme antiseptic precautions.—*British Medical Journal*, February 16, 1889.

Cocaine Poisoning.—Since the introduction of cocaine into the practice of medicine, so many cases of poisoning have occurred that it is important to analyze these for future guidance. It is the fate of nearly every useful but powerful drug, before its complete action is recognized, to be either too extensively or too recklessly employed. Perhaps this has been the case with cocaine, because it is commonly used for its local anæsthetic effect—to alleviate local burning, tenderness or pain—and for its anæsthetic effect prior to the extraction of teeth or other minor operations. Although these local uses are the chief ones for which cocaine is employed, yet it is important to bear in mind that it is a very powerful poison. When simply painted on to the parts serious results do not often ensue, except when applied to the pharynx or larynx in the form of spray. A tendency to syncope and complete unconsciousness may follow its use in this way. When injected under the gums for the extraction of teeth, or under the skin for the removal of a tumor or the opening of an abscess, great care is necessary in graduating the dosage, a fact by no means generally recognized. And this fact becomes all the more important when it is remembered that there is very great idiosyncrasy in the action of cocaine. A number of trials were made with cocaine by Decker, with the view of lessening the pain caused by hypodermatic injections of calomel; and he found that a dose of 0.05 gramme (three-quarters of a grain) ought never to be exceeded in a hypodermatic injection, and that usually half that amount, three-eighths of a grain, was safe to administer. This does not mean that a dose larger than three-quarters of a grain cannot be administered with impunity; but it is impossible to predict that a larger dose will not cause serious symptoms of poisoning.

Besides its action as a local anæsthetic, cocaine is a stimulant to the central nervous system first, and finally a paralyzer. It increases the respirations, and causes death either by respiratory paralysis, or more commonly, according to Mosso, by a tetanus of the respiratory muscles. Cocaine, moreover, paralyzes the vagus, causing extreme rapidity of the heart's beats; it raises the arterial blood-pressure, and increases the intestinal movements. It diminishes also the secretion of sweat and of saliva, and causes a considerable rise of body temperature. According to Mosso, cocaine is one of the most energetic substances known in causing an increase of the temperature.

In many of its actions, therefore, cocaine resembles atropine; in dilating the pupil, in stimulating the central nervous system, and finally paralyzing it; in paralyzing the vagus, in diminishing the secretions, and in increasing the intestinal movements. It differs from atropine in producing a contraction of the peripheral bloodvessels, while the primary contraction caused by atropine rapidly passes into dilatation. From this epitome of the physiological action of the alkaloid, the symptoms of poisoning in man are readily understood.

The question whether in a given case a drug will produce symptoms of poisoning or not depends chiefly on the dose given, but also on the mode of administration, and on the rapidity of elimination. Cocaine given hypodermatically is rapidly absorbed; it is also, in the healthy individual, rapidly eliminated by the kidneys. If, however, there is extensive disease of these organs, elimination will be prevented to a greater or less extent, and the symptoms of poisoning will be more serious. In a

recent case, in which twenty-two grains were accidentally administered by the mouth, the patient, a man, died almost immediately. At the post-mortem examination it was found that one kidney was tuberculous and the other was not functional owing to advanced atrophy, a condition of organs which would certainly prevent the rapid elimination of the alkaloid.

The slow elimination in other persons may explain some of the cases in which cocaine has caused poisoning. Mowat relates the case of a man, aged twenty-nine, in whom one drop and a half of a ten per cent. solution was injected at the sides of a rodent ulcer of the eyelid, previous to operation. The dose was only about one-seventh of a grain, but as the wound was being sewn up the patient became pale, and gasped for breath, while his legs were stiff and cold. The pupils were half dilated, and reacted to light; the pulse was weak and very frequent. The knee-reflex was exaggerated, and clonic spasms of short duration supervened. When these had ceased the patient appeared drunk, and, on recovery, was giddy for some time. It is unusual to observe such serious symptoms of poisoning from so small a dose. The great vascularity of the eyelid may have aided the rapid absorption of the poison. Poisoning, however, by larger doses is by no means uncommon. A dentist, for example, injected into the gums of a girl, aged nineteen, one grain and a third (0.1125 gramme) of cocaine in two portions. Anæsthesia was complete in a few minutes, and the tooth was extracted with ease. After washing out the mouth once or twice, the patient became very pale and fell into convulsions. Nitrite of amyl and cold affusions were tried, but had no effect in restoring the patient. She became unconscious and groaned, while the clonic spasms in the muscles of the body and extremities lasted for five hours. The pupils were dilated and did not react to light. At first the pulse at the wrist could not be counted, but afterward it was 176 in the minute. The temperature was raised, being 38.2° C. (100.8° F.), and the respirations were 44. The unconsciousness lasted two hours after the spasms had ceased. The patient recovered consciousness in seven hours, but was then unable to use the extremities. There was well-marked photophobia, diminished sensation in the hands, anæsthesia of the mucous membranes of the nose and mouth, and loss of smell and taste. The pulse was now 132, and the respirations 28 in the minute. Gradual recovery took place, but there was pain in the region of the heart for six days. During the first twenty-four hours after the cocaine had been given there was diminution of the amount of urine; there was also sleeplessness for thirty hours, and complete loss of appetite for four days. The patient was treated with large doses of opium, but no appreciable effect was observed.

In another case, where one grain and a quarter was injected for an acute attack of sciatica, there were soon great uneasiness and excitement, with a lively but constantly changing expression of countenance. There were choreic gesticulations with the hands; the pupils were irregular, the pulse very frequent, and the breathing rapid. Opium given in small doses was not of much benefit to the patient. Recovery did not ensue till four days after the poisoning, and even then the patient was restless and had a tendency to giddiness.

In a third case, a boy aged thirteen years received about one grain and a half at the side of a sebaceous cyst which was about to be excised; twenty-five minims of a solution of two grains in thirty-five minims of water were actually given. In five minutes the patient became pale and restless, so that the operation was rapidly performed. Dyspnœa ensued, and the pulse-rate rose to 120, while the restlessness increased, and the patient wrung his hands. The heart's action was very much disturbed, the pulse becoming so rapid as scarcely to be felt at the wrist; the respirations were frequent and irregular. In three-quarters of an hour there was nausea, with eructations and pain in the epigastrium. Brandy was administered, and the epigastrium rubbed. In four hours the patient was quite well. It was noticed that at the time of the operation the anæsthesia was not complete.

It is evident from these cases that any dose above one grain, whether injected into the gums or under the skin, may give rise to serious symptoms, happily, however, not fatal. The case of poisoning with one-seventh of a grain mentioned above was undoubtedly due to some idiosyncrasy on the part of the patient; the other cases of poisoning with doses above a grain tend to confirm Decker's statement that no dose over three-quarters of a grain ought to be administered hypodermatically. Indeed, it is not as a rule necessary to use a larger dose than this; if judiciously directed, the injection may be so made that complete anæsthesia will be obtained over a large area with even half a grain. The object is to obtain local anæsthesia without producing any of the general physiological actions of the alkaloid. In some cases the advent of poisonous symptoms seems unavoidable, and the question arises, What is to be done?

Morphine is to some extent an antagonist to cocaine, as it is to atropine; but no beneficial results appear to follow the administration of opium or morphine in cocaine-poisoning, even in large doses. Nitrite of amyl has been recommended as an antidote; it dilates the peripheral vessels, while cocaine contracts them. In cases of poisoning, however, it does not appear to have been of much use. The chief symptoms in severe cocaine-poisoning are referable to the nervous system; these are unconsciousness and convulsions. The latter, which are clonic in character, are cerebral in origin, since they are not produced in animals if the spinal cord be divided. However, death occurs either from respiratory paralysis, or perhaps more frequently from tetanus of the respiratory muscles. Cocaine, in fact, acts upon the central nervous system from above downward; it first affects the cerebral hemispheres, then the medulla oblongata, and finally the spinal cord. Chloral hydrate antagonizes all the actions of cocaine, except the rise of temperature. Although chloral itself produces a great fall of body temperature, it does not counteract the rise produced by cocaine. In poisoning by this alkaloid, Mosso, as the result of numerous experiments, advises the inhalation of ether or chloroform; in this way death by respiratory tetanus is prevented. When the patient is recovering somewhat, chloral in small doses may be administered. But prevention is better than cure; and there is no doubt that as great care ought to be taken in using cocaine for its local anæsthetic effect as in the exhibition of any other powerful drug, and especially is this the case when it is injected hypodermatically.—*British Med. Journal*, Feb. 9, 1889.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia.

SATURDAY, MARCH 9, 1889.

ERADICATION OF TUBERCULOUS DISEASE OF THE HIP-JOINT.

Gradually the evolving knowledge of joint disease and its pathology is being further elaborated into special applications and techniques for each individual joint. Heretofore the knee has had devoted to it a great amount of study and literature, but at present the hip is pressing more to the front —the operative treatment of the former having reached a high state of perfection.

An ideal result in the treatment of tuberculous disease of the hip-joint which has reached a stage justifying operation would be to open the joint, remove every particle of neoplasm, and secure primary union without drainage, with perhaps preservation of fair function of the articulation.

Such result Mr. Barker, *Lancet*, January 19, 1889, would seem to have attained in a series of cases by adherence to a technique which he describes, and by means of which he is confident of equally good results in a large proportion of all cases—more especially when, made bold by the assurance of good results, we may feel justified in operating at so early a time in the course of disease as we could desire. For realization of this are necessary: most rigid and perfect asepsis, complete exposure of the joint cavity and eradication of every particle of tuberculous material therefrom, together with avoidance of manipulation, and subsequent protection from infection.

Before incision the joint surroundings and everything liable to come in contact with it are made scientifically clean. After incision no antiseptics are used: nothing but an abundance of hot sterilized water, except just before closure of the wound it is to be mopped out with antiseptic solution and a little iodoform sprinkled over its surfaces. The incision used by Barker is that which was proposed by Heuter, of Greifswald, in 1878, which incision we think likely to become the accepted one for exploration or excision of the joint in question. It commences upon the front of the thigh half an inch below the anterior superior spine of the ilium and continues downward and a little inward for a distance of about three inches. In following this line the knife sinks between the tensor vagina femoris and glutei muscles on the outside and the rectus and sartorious upon the inner side; thus readily gaining ample access to the capsule without dividing any muscular fibres or other important structures. The joint opened and all purulent material washed away by a powerful stream of hot water, the neck of the femur is divided with a narrow-bladed saw in the direction of the cutaneous incision, and the head of the bone lifted out. Now begins the really vital part of the operation—the eradication of all remaining tuberculous material. The whole joint cavity is most thoroughly scraped or gouged out with what the author calls "flushing gouges." These Mr. Baker has invented for the purpose, although applicable to an infinitude of other uses and destined to become most valuable implements: consisting of the usual spoon gouge or curette mounted upon a long hollow handle having connection with a large elevated can of hot water by means of rubber tubing.[1] As soon as diseased tissues are cut away by the curette they are immediately flushed out and carried away by the powerful stream of water at all times rushing through the instrument.

It now simply remains to mop out the cavity with some powerful antiseptic, to sponge it dry and to dust lightly over the exposed surfaces a little crystalline iodoform, and to suture the wound edges firmly in contact without provision for drainage. Over this is placed a large antiseptic dressing so bandaged as to make uniform firm pressure upon all parts surrounding the wound, and the limb is abducted and placed upon a Thomas' splint. Theoretically a "cavity" remains, but practically it will be found that the wound surfaces are all in contact upon completion of the dressing. The dressing is to remain

[1] These irrigation curettes have been independently invented described and used by Auvard (Archives de Tocologie, No. 10, 1888).

on until the wound heals (which it should do in a very few days if we are to be successful); the splint for about three months, when the patient should be let run about without appliance.

A case is cited by Barker where a boy æt. five had developed abscess and other serious hip-joint disease in spite of a year's treatment upon a Thomas' splint. He excised the femoral head as above, secured primary firm union in ten days, and had the lad running about within as many weeks. At the time of writing his paper (six months after operation) the boy had no sign of disease about the joint, some motion, and but an inch of shortening.

If these brilliant results are as easy of attainment to all as they have been to Mr. Barker and his colleagues, verily a new era in the surgery of the hip-joint is at hand.

STATE REGULATION OF MEDICAL PRACTICE.

THERE appear to be a general repugnance to, and suspicion of, "mixed boards" for the regulation of medical practice, as a result of compromise legislation by the different States; yet it must be admitted that they do not always work badly. It is even claimed, in the instance of the Illinois board, that its efficiency has not been diminished, but rather enhanced by the commingling of regulars with irregulars in the administration of the medical-practice act; in that board there are not only a homœopathist and an eclectic practitioner, but also two laymen.

No one at all familiar with the achievements of this board will refuse to acknowledge that it has done much for the purification of medical practice in Illinois, in the face of very serious obstacles and of an exceptionally strong body of empirics. So many quacks were driven out of Illinois into adjoining territory that other legislatures have been impelled in self-defence to adopt similar laws, and there is very good reason for believing that the country at large has reaped this benefit, that the adoption of quackish practice as a means of livelihood has been discouraged, and that the proportion of "unqualified" practitioners is lower than at any former period of our history. Add to this the fact that in these States the standard of qualifications is not stationary, but is constantly, though gradually rising; and, as a result, the percentage of rejections by the colleges is rising also. The inferior class of students will find it more and more difficult to stand the tests, and will be forced to select other pursuits in life than that of medicine.

In Illinois, after two more years, a further advance has been provided for in the addition of a fourth year of professional study to the three that are at present required. A medical college "in good standing" will then be defined as one that requires four years of study under a preceptor and an attendance upon three full courses of college instruction as conditions of graduation. This new order of affairs will take effect after the close of the college session of 1890–91, and many of the schools are already so framing their curriculum that their graduates may be able to conform to the prospective standard raised by the "mixed board" of the Prairie State.

AT the meeting of the Trustees of the University of Pennsylvania, held last Tuesday, the following appointments were made: Dr. De Forest Willard, Clinical Professor of Orthopœdic Surgery; Dr. George A. Piersol, Professor of Histology and Embryology; and Dr. Samuel G. Dixon, Professor of Hygiene.

It is reported that the Trustees have under serious consideration the advisability of adding in the near future a compulsory fourth year to the medical curriculum.

It is stated that Mr. Henry C. Lea has given $25,000 to the Laboratory of Hygiene of the University of Pennsylvania on condition that an equal amount be obtained from other sources, and that a goodly proportion of this additional sum has been already raised.

The lectures on hygiene and laboratory work next year will be obligatory upon the first year's students at the University.

PRESIDENT GILMAN, in his address on Commemoration Day (February 22) at Johns Hopkins University, said that if $100,000 were added to the accumulated income remaining in the hands of the Trustees, that the University for the ensuing three years would not be hampered in its resources. More than half this sum has already been definitely pledged.

ACCORDING to the *New York Medical Journal*, at a special meeting of the Medical Faculty of Harvard University, held on February 23d, it was announced that Dr. Henry F. Sears had offered to present the school with $40,000, for the purpose of erecting a

pathological and a bacteriological laboratory. The matter was referred to a special committee. The plan proposed is to build a two-story annex to the present building, one story to be devoted to pathology, and the other to bacteriology, and to fit up a gymnasium for the students in the basement.

A BUILDING site of 75 feet by 100 feet, with the privilege of an additional 25 feet, it is stated, has been secured on West Forty-third Street, near Fifth Avenue, for the new building of the New York Academy of Medicine.

WITH the wish to promote research in certain departments of physiology, and to aid in defraying its cost, a member of the American Physiological Society has offered two hundred dollars for the best research or researches bearing on one or more of the subjects stated below, viz.:

"The rate of transmission of nerve impulses, afferent and efferent, and the duration of reflex and reaction time in the higher animals, especially man; also the conditions, normal and pathological, which alter such rates and times."

The competition is limited to residents of North America, and the prize will be awarded for original work done after January 1, 1889. The award will be made by those persons who, on October 1, 1890, constitute the Council of the American Physiological Society. In making its award, the Council will take into consideration researches of which printed or legibly written accounts, marked on the outside "Nerve Physiology Prize," have been received by the then Secretary of the Society before October 1, 1890.

To obtain the prize, a research must have a direct bearing on human physiology, and good researches on man will be preferred to similar researches on other animals; but experiments on mammals other than man, if applied to the interpretation of the phenomena of the human body and supplemented by observations on man, will have weight. Previous publication will not debar a research from the competition, provided the work has been done after January 1, 1889.

The Council reserves the following rights: to withhold the prize if, in its opinion, no research presented is sufficiently worthy; to award only a part of the prize if, in its belief, a research, though meritorious, does not deserve the whole; to divide the prize between two or more candidates in ratios which seem to it just; and if it think it desirable, to require a competitor to demonstrate his experiments to a committee appointed by the Council.

For the present, communications concerning the prize should be addressed to H. Newell Martin, Secretary, Johns Hopkins University, Baltimore, Md.

The Eighteenth Congress of German Surgeons will be held at Berlin on April 24 to 27. Professor von Esmarch will open a discussion on the etiology and diagnosis of carcinoma, especially that of the tongue and lips. An effort will be made to collect the statistics of cases of carcinoma of the tongue, intestine, and stomach, in which more than three years have elapsed since the first operation and in which there has been no recurrence of the disease.

BY the will of the late Alexander Murray, of Montreal, the General Hospital of that city will receive the sum of $750,000. This is the largest gift hitherto made in Canada for any public charity, with the exception of the joint donation of Sir Donald A. Smith and Sir George Stephen of a million dollars for the founding of the Royal Victoria Hospital, also of Montreal.

DR. DAVID FERRIER has been appointed Professor of Neuro-pathology in King's College, London, and has resigned the Chair of Forensic Medicine in the same institution. It is stated that some provision will probably be made for supplying Dr. Ferrier with the means of carrying on pathological and physiological research in connection with this chair.

SOCIETY PROCEEDINGS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, February 13, 1889.

THE PRESIDENT, W. W. KEEN, M.D., IN THE CHAIR.

DR. W. W. KEEN read a preliminary report on a case of

TAPPING AND IRRIGATION OF THE VENTRICLES.

Last fall he made a proposition for tapping the lateral ventricles. At that time he was not aware that the procedure had ever before been suggested, but he has recently learned that, in 1881, Wernicke suggested it in a general way, and by the lateral route. He, however, first formulated general rules, which have stood the test of actual trial. The operation, he believed, was never performed until he did it in a case of marked choked disk on both sides, with complete blindness dating from last

Christmas, which he had the opportunity of seeing through the politeness of Dr. Strawbridge. He tapped the ventricle five weeks ago last Friday, reaching it by the lateral route, at a depth of one and three-fourths inches from the dura mater. A half-inch trephine opening was made, a crucial incision in the scalp and dura being employed, as he intended to keep up drainage. From two to four ounces of cerebro-spinal fluid escape from this opening daily.

The case was examined from day to day to see the effect on the swelling of the optic disks. Before the operation this amounted in one eye to 2.3 mm. and in the other to 1.8 mm. After the operation, it eventually fell to 0.83 mm. on each side. At the end of a week the horse-hair drain, which was introduced at the time of the operation, was substituted by a rubber drainage tube passing into the ventricle. The discharge then became freer, amounting from four to eight ounces per diem.

In addition to this, he explored with a probe the occipital lobe on the left side, twice to a depth of three and a half inches, but found no tumor. He then made a small opening by a gouge under the cerebellum on the left side, and explored the left lobe, and then passed obliquely into the right side, but no tumor was found.

On February 8th he trephined the child on the opposite side, thinking that there might be a tumor in the posterior lobe on that side, but he found none, though he touched the tentorium and the falx. He then tapped the lateral ventricle on that side. On February 12th he washed out the lateral ventricles, passing about eight ounces of a solution of boracic acid (four grains to the ounce) from one side to the other. There was some little irritation resulting from the manipulations, but the moment the warm solution began to pass through the ventricles the child settled itself into a position of complete comfort.

He exhibited a bottle of the cerebro-spinal fluid, which had been standing on his desk for a week. There were no signs of decomposition. The fluid contained both sugar and albumin. This, with its continuous flow, proves it to be cerebro-spinal fluid. The child did not suffer any notable rise of temperature after any of the operations, with the exception of the last one, when there was a temporary sharp rise to 104°.

CORRESPONDENCE.

THE MODUS FACIENDI OF THE PASTEUR METHOD AGAINST HYDROPHOBIA.

In a preceding article, on the inauguration of the Pasteur Institute, I gave a very superficial description of the different departments which, at present, constitute this institution. To-day I intend to examine more carefully one of the most important of these departments, the one which has attracted the attention of the scientific world for several years past, namely, the section devoted to the treatment of hydrophobia. Considering rapidly the statistics, I shall next give in as detailed a manner as possible, a full description of the method of preparation of the virus of different strengths employed, and the *modus faciendi* of the inoculations.

Very much has been said and written for and against M. Pasteur's method since the time he made his first communication to the Académie des Sciences, in October, 1885, when he presented the results of his first and successful inoculations performed on the young shepherd Meister, who had been most seriously bitten by an hydrophobic dog.

I shall not attempt to make a critical study of all that has been written against this method, as most of these articles, if carefully examined, show that their authors, even amongst Paris physicians, are nearly, if not entirely, ignorant of the practical application of the method, having never seen it applied, not having followed its results, not even knowing the kind of virus used for inoculations, for I have myself met several of these violent contradictors who were convinced that men were inoculated directly from the virus just obtained from the cerebrum of a dog which had just died from hydrophobia—which is far from being so.

Some have objected to the method, since a certain number of patients, who were inoculated to prevent the development of the disease, died anyhow. Is there a physician or a surgeon who can mention one single method of treatment which, applied to a particular disease, would give him a percentage of favorable results equal to 100 per cent.? I am afraid not. Others have gone so far as to say that the inoculations produced the disease. In no case has it been found, up to now, that such has been the case, and that one person should have died as a result of a previous course of inoculations. There is an experimental test to prove this fact, which I shall give further on, when the method of preparation of the virus shall have been described.

In this connection, however, I might mention this interesting fact, that most of those who are engaged in the experiments connected with the scientific researches of hydrophobia have inoculated themselves as a preventive against the danger which might arise from a manipulative wound—among these are M. Pasteur's able collaborators who have undergone these inoculations, and who, luckily for themselves and for the scientific world, have not had to regret it.

Let us now come to the statistics of the Institute, and compare the percentage of deaths by hydrophobia before and after the introduction of the new method.

The rate of mortality for ordinary bites or those made through clothing, was agreed in every country as varying from 10 to 20 per cent., while the percentage of deaths from bites involving the exposed parts, face and head, was recognized as being from 80 to 88 per cent.

The following are the statistics of the Pasteur Institute:

In 1886, 2682 persons were inoculated, with a death-rate of 1.34 per cent.

In 1887, 1778 persons were inoculated, with a death-rate of 1.12 per cent.

In 1888, first six months, 914 persons, with a mortality of 0.77 per cent.

These percentages contain even the cases of persons who died on the second day of the treatment, and it has been asserted by Dr. Gamaleia, of Odessa, and Professor Grancher, of Paris, that the treatment is of no avail if begun when the virus has already reached the nervous centres. Their assertion is founded on the following experiment: if one inoculates directly on the surface of the cerebrum of a healthy dog the nervous matter obtained from the cord of a rabid dog, although the virus is placed immediately in contact with the cerebral surface, the first symptoms of the disease will present them-

selves only from the fifteenth to the eighteenth day after inoculating. Admitting this to be the case in the human subject, and if we deduct from the above table all those who have died within fifteen days after the beginning of the treatment, the percentage comes down to

0.93 per cent. . . . . in 1886.
0.67 per cent. . . . . in 1887.
0.55 per cent. . . . . in 1888.

An interesting and practical proof of the value of the method is illustrated by the following fact:

In Naples, from September, 1886, to January, 1888, 199 persons were inoculated, with a percentage of deaths of 1.58 per cent. In January, 1888, the municipality refused financial aid to the inoculating institution, which, therefore, was closed, and remained so until September, 1888. During this period of nine months, nine deaths occurred in non-inoculated persons from hydrophobia. The municipality then immediately asked the director of the institution to reopen it.

A medical journal of Vienna, the *Wiener medicinische Presse*, said in one of its articles that, contrary to what Professor Grancher had asserted in his speech, no antirabic institute existed in Vienna. This paper, however, is quite mistaken, for Dr. Uhlman, a physician who has occupied himself with this method in the Austrian capital, wrote to M. Pasteur, on November 19th, that from September, 1887, up to date, he had inoculated thirty-one persons, who all remained perfectly well.

Finally, what better proof of the success of the method can one give than to mention the following communication which was read lately before the Académie des Sciences, by a foreigner, a Russian, Dr. Odo Bujroid, from Warsaw?

"I begun the antirabic treatment in Warsaw on June 29, 1886, a few days after my return from Paris, where I had studied the method under M. Pasteur from June, 1886, to January 1, 1887. I treated 104 persons bitten by rabid dogs, or suspected to be such. I admitted every person to the treatment, even those whose wounds were slight; I refused only those who had been recognized as having been bitten by healthy dogs. During these six months I applied the *simple treatment* of M. Pasteur, which treatment begins with the inoculation of the cord of fourteen days and finishes with the fifth day cord, only one inoculation a day being made.

"On November 23d I had my first case of death, a boy of eleven years, Arthur Stolay, bitten severely on the exposed right forearm; the treatment was only begun nine days after the bite.

"After this case of death, and influenced by the researches of M. Frisch, from Vienna, in regard to the application of the antirabic treatment, I determined to try a still weaker treatment, and I did not inoculate cords of less than six or seven days old. We know that these cords contain so little virus that Professor Frisch himself recognized them to be devoid of danger.

"As formerly, I admitted to treatment persons who had been lightly bitten, and refused only those who were recognized to have been bitten by healthy animals. During seven months I inoculated in that manner 193 persons, 5 of whom had been severely bitten in the face. As a result of this light treatment I had, notwithstanding the treatment, 8 cases of death by hydrophobia; amongst these were the 5 who had been bitten at the face, and 3 bitten severely on the forearm.

"During the first days of August, 1887, two persons presented themselves who had been very severely bitten on the head and face by a wolf, whose hydrophobia had been experimentally demonstrated by inoculation in a rabbit. As I had observed that in cases of severe bite of the face, the light treatment was of no avail, I applied, for the first time, to these two patients a treatment which differs very little from M. Pasteur's *intensive treatment*.

"I made my inoculations with cords from twelve to three days old, performing these inoculations twice a day, and repeating the series three times.

"First day, morning, cord of twelve days; evening, cord of ten days.

"Second day, morning, cord of eight days; evening, cord of seven days.

"Third day, morning, cord of six days; evening, cord of five days.

"Fourth day, morning, cord of fourth day; evening, cord of three days.

"This series was repeated three times in twelve days.

"One month later I received two persons bitten still more severely by a female wolf, whose bulb had been inoculated in rabbits and produced hydrophobia. The treatment followed was the same as the preceding, but as the outside temperature was very high, and I found that the virulence of the cord is much reduced in hot days, I even inoculated in one case a two days' old cord. These four persons remained perfectly well, as is proven by the letters which I received from the Chief of the District of Chetm (government of Lulin, Russia).

"Since I began this intensive treatment, we have treated already *three hundred and seventy persons, thirty of whom were bitten in the face or head, with not one single case of death*.

"We begin our treatment always with the cord of ten days in summer and twelve days in winter, and complete it with the cord of two days in summer and three days in winter.

"Let me remark that in Warsaw we desiccate the cords at a temperature of 61° to 67° Fah., and in that manner they keep their virulence much more powerful than those which are preserved at 74° Fah., as is ordinarily done.

"Using the method just described, sixteen months have elapsed without one case of failure.

"Actually I make a very rigid choice of the bitten persons; I refuse to treat those who are bitten by animals who were little suspected to be suffering from hydrophobia, or whose clothes show no apparent sign of tear. In this manner I have refused to treat 160 persons, who naturally remained in perfect health.

"The 370 persons who form the last portion of my statistics, have been bitten by animals which were certainly suffering from hydrophobia, and which had inflicted very severe bites.

"In that same period of time which corresponds to my statistics, eight persons not treated have died from hydrophobia in Warsaw or its surrounding districts. This number represents only a part of the cases of hydrophobia non-treated, for it contains only the persons who presented themselves at the institute with the symptoms of the disease already present, and those of whose death we had been notified by persons bitten by the same animal and who had undergone the treatment.

"The application of the *intensive method* has not only proven itself to be devoid of danger, but also to be perfectly efficacious."

We shall take now into consideration the mode of preparation of the virus which is to be used for the antirabic treatment applied to the human subject. The inoculating virus is not derived, as is too often erroneously supposed, directly from the hydrophobic dog, and then injected directly into man; but the medulla of the mad dog is first inoculated in a rabbit; when this animal dies from the disease, another rabbit is inoculated with a portion of the spinal cord of this dead rabbit, and so on, the disease is allowed to pass through a long series of rabbits, until the moment has come when the time of incubation of the disease can be no more reduced, and that is, when the symptoms of hydrophobia make their invariable appearance on the seventh day, and the animal dies on the tenth from the paralytic form of the disease. Now is the time when the spinal cord of this rabbit is taken and prepared, as we shall describe further on, for the production of the virus for inoculations.

Passing next to the details of the manipulations. The first step is the removal or extraction of a certain amount of the nerve tissue from the brain of the hydrophobic dog. To accomplish this, the dog is placed on his abdomen, and, while an assistant steadies the head with a strong pair of forceps, the operator, after having removed the skin from the head, opens the skull with bone forceps. The brain and medulla are then carefully removed and placed on a previously sterilized plate, the lower surface of the brain directed upward.

We do not think it superfluous to recommend to the operator the utmost care while he is handling the anatomical pieces; in fact, his hands need never touch any of the brain during the extraction. The slightest abrasion on a hand or finger might be the starting-point of the inoculation of the disease. As I have already said, certain experimenters, to do away with the continuous fear of accidental inoculations during their experiments, have preferred to undergo a course of preventive inoculation.

For safety, it would be well to wrap the dead rabid animal in an antiseptic linen or paper, as is done at the Pasteur Institute; but *antiseptics must not* be used to render the instruments aseptic, or anything that comes in contact with the nerve matter, for fear of their neutralizing the condition of the tissues. Every instrument, every plate or bottle that is to receive nerve matter, must be sterilized by heat alone, and placed in a sterilizer for half an hour at a temperature of 248° to 266° F.

Returning to the brain of the dog, after it has been placed in the sterilized plate, the next step consists in exposing the floor of the fourth ventricle, from which situation a portion of nerve tissue the size of a pea is taken; to expose the floor the free portion of the medulla is seized with forceps, lifted and turned on the anterior portion of the brain, when the ventricle will be exposed. Two of these fragments are then taken in this situation and placed on a small glass which has been previously sterilized; veal broth is then added, drop by drop, while the operator with a glass rod triturates the small fragments into a pulp. This pulp is stirred continuously until two or three drachms of the broth have been used; two drachms if only two fragments of the size of a pea have been used; three drachms if three fragments have been employed.

The veal broth is prepared by taking one kilogramme (two pounds eight ounces Troy weight) of veal, to which one litre (one quart) of water is added; the bones, tendons, and fat are first separated from the meat and thrown away; while the meat itself is cut into many small pieces. These pieces are then placed in the above-mentioned quantity of water, placed on a very small fire, and stirred continuously until it begins to boil. This broth is then carefully filtered on the ordinary filter paper, and is next placed into small bottles, the mouths of which are closed with cotton-wool. These bottles, with their contents, are next heated to a temperature of 248° F. for one-quarter to half an hour, when all the germs which they may contain have certainly been destroyed.

The virus, prepared as above described, is now ready for inoculation on the first rabbit; the operation is done as follows: The rabbit is fixed on a table, abdomen downward and legs extended on each side, and firmly fixed to the side of the table; he is placed in that position so that we may have easy access to the upper part of the head. Chloroform is now administered, and as soon as anæsthesia is obtained an assistant takes hold of the head of the animal to steady it, while the operator proceeds to the shaving of the operative field, and then makes an incision of three-quarters to one inch in length down to the bone, starting from the centre of an imaginary line uniting the two eyes and extending the incision therefrom upward. The lips of the wounds are then separated by means of hooks by the assistant, while the surgeon applies his trephine at about the middle of the incision. This opening must be at least one-third of an inch in diameter; the disk of bone is next removed, taking great care not to injure the brain membranes. The hypodermatic needle is next introduced through them, and two drops of the virus, prepared as above cited, are introduced after the needle is withdrawn. This external wound is washed carefully with a solution of carbolic acid, 1 in 40, and finally sutured.

The rabbit is then placed in a cage, which is kept very clean; the animal is kept under close watch. This rabbit will, in all probability, show signs of the disease after an incubation of fifteen days and die.

A portion or fragment of this dead rabbit's cord is then taken, prepared in a solution as mentioned above, and inoculated into the arachnoid space of another rabbit; when this newly inoculated one becomes rabid and dies of the disease, a portion of his nerve matter is again inoculated to another healthy rabbit; and so on, is the series continued, and it is found that after the twentieth to the twenty-fifth passage the rabbit shows invariably the signs of the disease on the eighth day. If the inoculation is continued to a still further series of rabbits, say to the fiftieth passage, it is found that the incubation of the disease is reduced to seven days and the animal dies on the tenth. This is the shortest inoculation obtained, for M. Pasteur, after having continued his inoculations to the one hundred and fiftieth passage, still found the incubation of the disease to remain at seven days.

The object of the inoculation of the virus of the rabid dog to the rabbit is not, as is often erroneously believed, to weaken the virus; on the contrary, the cultivation, so

to say, of the virus in the species rabbit, produces an increase in the virulence of the hydrophobia virus so far as one is able to judge by the first described series of experiments on rabbits, for we have seen that the direct inoculation of the virus derived from a hydrophobic dog shows itself in the rabbit after an incubation of fifteen days; while after the disease has passed through forty or fifty rabbits, the inoculation is reduced to seven days.

This increase of virulence is also observed in guinea-pigs, in which species the incubation even reaches five days. In certain other species, however, by a succession of passages from one animal of the same kind to the other, the time of incubation is progressively postponed and the virus therefore progressively attenuated. Monkeys belong to that class; a monkey inoculated with the virus obtained from a mad dog, takes the disease in eleven days, nerve matter taken from the medulla of this monkey inoculated to another monkey makes the disease appear in twenty-three days; and so on, the period of incubation is progressively postponed.

Having obtained, after this numerous succession of passages, a minimum time of incubation in rabbits of seven days, the seventh day rabbit's spinal cord, which by experiment has been shown to be virulent to the same degree throughout, is the one used for the preparation of the virus employed for human inoculation.

If a solution from this fresh cord should however be made, we would have the strongest, the most powerful solution of nerve matter, capable of giving the most severe form of hydrophobia, much worse probably than the one originated through a bite from a hydrophobic dog, as has been shown on lower animals.

The virulence of this cord for human inoculation must be graduated, and M. Pasteur has found that the desiccation of such a cord, by being suspended in a bottle containing caustic potash, can be realized to such a degree, that one can graduate the virulence of such a cord according to the number of days it has been exposed to the desiccating process, from its maximum intensity in the fresh state to its complete neutrality after a certain number of days of desiccation. Temperature slightly influences this process, for it has been found that the cord remains virulent longer in winter than it does in summer.

Returning, after this digression, to the rabbit dying on the tenth day after seven days' incubation, one must proceed to the extraction of the spinal cord. The animal is placed as before on the abdomen, the skin is cut open on the back and removed; the spinal canal is next exposed, by cutting alternately with forceps the spinal processes; when the cord is exposed it is to be freed from its attachment from below upward for about four or five inches, and is removed from the spinal canal.

This portion is then carefully placed on a sterilized plate, and to one end of it a sterilized thread is next attached, which is for the purpose of suspending the cord in the desiccating bottle.

The desiccating bottle holds about one-quarter, is broader than an ordinary wine bottle and has two openings, one at the upper part, the other below and laterally; the object of these two openings is to allow the passage of a draught of air; each one of these openings is kept closed by cotton-wool, as used in bacteriology for closing the test or culture tubes. At the lowest part of the bottle, small fragments of caustic potash are placed, for the purpose of keeping the air absolutely dry. The cord is then introduced by the superior opening, and by its suspending thread is fixed to the sides of the neck of the bottle, while the opening is immediately closed with cotton-wool.

To make the first inoculation in man, the fresh cord is introduced into one of the desiccating bottles and left in it *fourteen* days, after which time it is found to be almost completely dried up, of a blackish appearance, brittle, etc.

Let us suppose that six persons who have been bitten present themselves on the same day for treatment. They will all receive on that first day a solution of a cord which has been desiccated for fourteen days; this is called the "fourteen days' cord." Having six persons to treat, we shall detach about six millimetres in length (one-quarter of an inch) of this fourteen days' cord, and allow it to fall in a small conical sterilized glass. We next, with a sterilized glass rod, triturate this cord and add drop by drop our veal broth, until we obtain a little more than six cubic centimetres (ninety minims), say about seven cubic centimetres (one hundred and fifteen minims). The glass is now covered with a filter paper and the solution is ready for inoculation. One cubic centimetre, or about sixteen minims, of this liquid is introduced into each patient; this is the first day's treatment.

When these six persons present themselves again on the second day, they will receive an injection from the solution of a cord which has remained only thirteen days in the desiccating bottle. On the third day of treatment, the twelve days' cord will be used; on the fourth day, the eleven days' cord; and so on until the third day cord in summer, or fourth or fifth day cord in winter shall have been used.

M. Pasteur first started his method of treatment, by the so-called "Simple treatment," which, as we have just now described, consisted in making one daily injection, beginning by the fourteen days' cord, and finishing by the first day one. As a type of this treatment, we have the history of the treatment of his first patient, the young shepherd, Joseph Meister, who was bitten on July 4, 1885, by an hydrophobic dog, on the hand, legs and thighs; he received fourteen wounds. Professors Vulpian and Grancher, having been called in by M. Pasteur, expressed their opinion that according to the severity, seat, and number of his wounds, this young boy was almost certainly condemned to be taken with the disease and die. M. Pasteur, after having narrated the results of his researches to the above named professors, was encouraged by them to use the inoculations, which from that day were made by Prof. Grancher—M. Pasteur not being a physician.

This young man was bitten on July 4th, at 8 A.M., and his treatment was begun only on July 6th, at 8 P.M. The whole treatment of the case was as follows:

On July 6th,	8 P.M.,	½	c. cm. (8 minims)	of the	15	days' cord.
" 7th,	9 A.M.,	½	"	"	14	"
" 7th,	6 P.M.,	½	"	"	12	"
" 8th,	9 A.M.,	½	"	"	11	"
" 8th,	6 P.M.,	½	"	"	9	"
" 9th,	11 A.M.,	½	"	"	8	"
" 10th,	11 A.M.,	½	"	"	7	"

On July 11th, 11 A.M.,	½	c.cm. (8 minims)	of the	6 days'	cord.
" 12th, 11 A.M.,	½	"	"	5	"
" 13th, 11 A.M.,	½	"	"	4	"
" 14th, 11 A.M.,	½	"	"	3	"
" 15th, 11 A.M.,	½	"	"	2	"
" 16th, 11 A.M.,	½	"	"	1 day	cord.

This young man is doing well to-day, and the inoculations have not given him the disease, although the same solutions used on him of the 6th, 5th, 4th, 3d, 2d, and 1st days, have invariably given hydrophobia to the rabbits to which they were injected; the 1st and 2d day cords, produced the disease in rabbits on the seventh day; the 3d and 5th day cords produced it on the eighth, and the 6th day cord on the fifteenth day.

To-day M. Pasteur has entirely given up the so-called "simple treatment," and resorts exclusively to the "intensive treatment," in which the cords of one and two days are no more used, M. Pasteur having found that the 3d day cord in summer, and the 4th and even the 5th day cord in winter, had the same strength as the one day cord. The intensity of the treatment is in accordance with the severity of the bites, the treatment being more severe for bites of the exposed regions, face, head, and hands, and much less so for bites of parts protected by clothes. The description of the intensive method, as given by M. Pasteur in his communication to the Académie des Sciences, in October, 1886, was as follows:

"On the first day of treatment, for persons bitten on the face or head, the cords of twelve, ten, and eight days will be inoculated successively at 11 A.M., 4 P.M., and 9 P.M. On the second day, the cords of six, four, and two days at the same hours; and on the third day, the first day cord. The series is then taken up again on the fourth day, the cords of eight, six, and four days; on the fifth day, the cords of three and two days; on the sixth day, the one day cord; on the seventh, a cord of four days; on the eighth, a cord of three days; on the ninth, a cord of two days; on the tenth, a one day cord." This treatment, in three series, is done in a period of ten days.

The inoculations are performed at the Institute Pasteur exclusively; every one who desires to undergo the treatment must come to the Institute.

For nearly two years the inoculations were made by Prof. Grancher, of the Paris Faculty of Medicine; while he still superintends this service, the inoculations are now performed by Dr. Chantemesse and Dr. Charin.

On the physician's table very few instruments are to be found; a series of hypodermatic syringes which, needless to say, have been previously well sterilized, then a flask of hot water, kept continuously at the boiling temperature, and containing suspended in it a test tube filled with oil; this hot oil is for the purpose of dipping into it the hypodermatic needle, immediately before each inoculation, to sterilize it perfectly. On the same table we find a vase containing a solution of an antiseptic, carbolic acid usually, which is for the purpose of washing the parts before the injection is made.

The injections are made into the abdominal wall, right and left hypochondriac regions alternately, to prevent too great irritation of the injected parts. Sometimes local inflammation is produced, slight swelling and redness are observed; the patient is immediately ordered to take a full hot water bath, which in the great majority of cases will remove this slight annoyance.

The patients are divided into a certain number of sections, according to the number of days they have been under treatment. The physician always begins to inoculate first those who present themselves for the first time, and who, therefore, receive the weakest virus; and always ends by those who receive the most powerful virus. The reason for this lies in the fact that, by injecting the weaker virus first, there is no danger for the next series of patients, if some of this virus should remain by mistake in the hypodermic syringe; while, on the contrary, if the inoculations were begun by the stronger virus, there would be danger for the next series, who would not be ready for the strong virus in case some of it remained in the syringe.

The solution of virus is contained in a corresponding number of glasses, as there are different cords to be inoculated, and each one is covered and closed by filter paper; the syringe is filled by passing the needle through the filter paper, which precaution prevents the virus from being contaminated by impurities of the atmosphere. The quantity of virus injected is one and a half cubic centimetres, or twenty-three minims, at each inoculation made with the *weaker* virus; but only one cubic centimetre, or fifteen minims, of the *stronger* virus is injected at one time

Before closing, let me refer to the experimental test, that exists to assure us that a person will not die from the effects of inoculations, as has often been proclaimed against the method.

If the fragment of a cord, obtained from a dead hydrophobic rabbit, from the same that will be used to prepare the human virus, is inoculated to a healthy rabbit, this animal will present symptoms of the disease on the seventh day, and die on the tenth.

If, instead of inoculating this fragment of cord in a rabbit, it is inoculated in a dog; this dog will present the first signs of the disease, not on the seventh day, but on the twelfth day, and die shortly afterward.

The test lies in the following experiment: If a fragment of the cord of this dead dog is inoculated anew in a rabbit, this animal will take the disease on the seventh day and die on the tenth; showing that the rabbit virus has really been the cause of death in the dog; while if the rabbit had been inoculated with the cord of a dog which died from the ordinary street hydrophobia, he would only have shown signs of the disease on the fifteenth day.

This test has been applied to every dead person who had been inoculated, and has never shown that any of them had died from the result of rabbit hydrophobia.

ARTHUR V. HUGENSCHMIEDT, M.D.

NEWS ITEMS.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM FEBRUARY 26 TO MARCH 4, 1889.

By direction of the Secretary of War, WILLIAM O. OWEN, Jr., *Captain and Assistant Surgeon*, is relieved from duty at Fort Leavenworth, Kansas, and will report in person to the commanding officer Fort Gibson, Indian Territory, for duty at that post, relieving Captain and Assistant Surgeon C. N. B. Macauley, who, on being so relieved, will report in person to the commanding officer Fort Leavenworth, Kansas, for duty at that post.—Par. 3, *S. O. 48, A. G. O.*, February 27, 1889.

ACUTE PANCREATITIS.

A Consideration of Pancreatic Hemorrhage, Hemorrhagic, Suppurative, and Gangrenous Pancreatitis, and of Disseminated Fat-necrosis.

The Middleton-Goldsmith Lecture for 1889, delivered before the New York Pathological Society, Feb. 16, 1889.

BY REGINALD H FITZ, M.D.,

SHATTUCK PROFESSOR OF PATHOLOGICAL ANATOMY IN HARVARD UNIVERSITY AND PHYSICIAN TO THE MASSACHUSETTS GENERAL HOSPITAL.

(Continued from page 262.)

GANGRENOUS PANCREATITIS.

BUT the subject of acute pancreatitis deserves attention from another event, viz., its possible termination in gangrene. The earlier medical writings contain occasional references to gangrene of the pancreas, but the evidence presented is so slightly objective as to make them of but little value for present needs.

Grisellus,[1] for instance, has been generally considered to have called attention to this matter.

His patient, a man forty-two years of age, suffered from frequent colic, which was easily relieved. He was suddenly, without cause, seized with a chill and severe colic, and died quietly in the course of eighteen or nineteen hours. The post-mortem examination showed an extreme quantity of abdominal fat. The pancreas was found sphacelated, in a large mass of fat. "In whose absence nature had supplied another like round mass, on the right toward the liver and attached to the sphacelated part. Veins ran through the middle, like Wirsungian ducts, but without order. This sphacelated pancreas distributed a like contagion, penetrating not only adjacent parts, but even the diaphragm, consuming the left lobe of the lung as in phthisis." The liver is said to have resembled grumous blood, in color and in substance. There were several calculi in the gall-bladder. "Other membranes were adherent at the bottom of the gall-bladder, and held another stone larger than all."

Although the evidence does not permit an exact diagnosis to be made, it would seem as if the sufferings and death of this individual were rather attributable to biliary calculi than to pancreatic disease. The penetration of the diaphragm and the consumption of the left lung suggest that post-mortem softening of the stomach may have aided in producing the described appearances. The clinical history, brief as it is, affords quite a different picture from that to be presented as connected with pancreatic gangrene.

Bonetus[2] credits Barbette with stating that in a case of obstinate vomiting the pancreas was found wholly putrid, rather sphacelated. Again,[3] he refers to the statement of Verzaschka that Glaserus found a semi-putrid pancreas in a case of dropsy.

Bonetus himself[1] records a case of dropsy in a boy in whom the pancreas is stated to have been semi-putrid.

In Lieutaud[2] there is extracted the case of a woman with obstinate vomiting, severe renal symptoms, and pubic pain, in which the pancreas was semi-putrid, almost destroyed.

Also[3] that of a girl with swollen abdomen, hypogastric pain, purulent urine, and diarrhœa. The omentum and a large part of the mesentery were rotten. The liver filled almost the entire abdominal cavity. The pancreas was putrid, and the whole left kidney purulent.

Again,[4] in an infant, with dropsy, there were found a putrid omentum and pancreas. He reports[5] that Helvigius found a sphacelated pancreas, omentum, and mesentery, also a shrivelled and putrescent liver, with a gall-bladder containing more than a hundred calculi, in a man sixty years of age, who was seized with gastric pain, obstruction of the liver, and dyspnœa; there were black jaundice and œdema of the legs.

He also[6] refers to a case of extreme dilatation of the bile-duct, where the head of the pancreas was swollen, dense, scirrhous, and pressed upon the opening of the cystic duct. The left portion of the pancreas was putrid. Finally, he credits[7] Bonetus with reporting a case of oft-recurring, obstinate, tertian fever, in which the pancreas and mesentery were found somewhat corrupted and sanious.

Schmidtmann[8] speaks of finding induration of the pancreas with inflammation and beginning gangrene in a case of chronic, suppurative nephritis with destruction of the bladder.

The case reported by Portal[9] is perhaps the first which demands recognition as illustrating the relation of pancreatic gangrene to hemorrhagic pancreatitis. He writes as follows:

"Gangrene of the pancreas is the frequent result of inflammation. I have found it in several corpses, and especially in that of a merchant of St. Denis Street, who, during a period of more than two years, suffered from severe attacks of colic. They were deep-seated, below the navel, and were often preceded or followed by nausea or vomiting. There was neither swelling nor induration of the lower abdomen; no dryness of the tongue, nor thirst. He became much emaciated, the pains increased, the pulse quickened, the heat of the skin became acrid and very strong. The slightest touch of the lower abdomen became very painful. The urine was scanty and red. This state lasted some twenty days, when the patient died unexpectedly. I was present at the autopsy. The pancreas was violet-red and soft, a black moisture

escaped from its surface, it was almost wholly gangrenous. The stomach and the duodenum appeared inflamed in places."

Although the above case is probably one of the disease now under consideration, the lack of detail in the clinical statement and account of the anatomical appearances makes it value rather historical than useful in determining the relations of the hemorrhage to the gangrenous affections of the pancreas.

Gendrin[1] reports a case which is likely to belong to the series, but which is deprived of a considerable part of its possible value by the lack of sufficient details, clinical as well as anatomical. He states, "we have seen a vast cavity in the region of the pancreas communicating with the jejunum, which was perforated an inch from its origin. The pancreatic tissue was lost in a dense, friable, reddish mass which formed the wall of the cavity, which was filled with a grayish, very fetid pus. The surrounding cellular tissue and the intestinal walls united in forming this suppurating tumor.

The following fifteen cases of pancreatic gangrene represent all, with the above possible exceptions, I have been able to collect. Twelve of them have been observed in the past eight years, five of them have occurred in Boston or its vicinity, and three of them are now published for the first time.

Case LVI.—Male, aged sixty-three. Always well. For sixteen days gastric disturbance, vomiting. Now pale, cachectic, thin; yellow, bitter vomit. Epigastrium somewhat distended, tense, tympanitic, sensitive. Abdomen elsewhere moderately swollen. In the evening repeated nausea, vomiting, great prostration, collapse, violent epigastric pain, thence extending over whole abdomen. Traces of blood in vomit. No albuminuria. Death, after rapid collapse, on the eighteenth day. The pancreas a thin, flabby, friable, grayish band soaked in fluid. It lay in an ichorous cavity, bounded by the posterior wall of the stomach, spine, spleen, and duodenum, and communicating with the stomach by three openings in its posterior wall. The pancreas was united in front by a few shreds to the omental bursa. Its cells were either disintegrated, or swollen, or opaque. Certain lobules were separated from each other, in part collapsed, with intervening molecules and fat-drops. Pus-cells were present. Splenic vein obstructed by a dark-red thrombus extending to the portal vein.—Haller and Klob. *Zeitschr. d. k. k. Ges. d. Aerzte zu Wien.*, 1859. xv. 577.

Case LVII.—Male, aged fifty-two. Digestive disturbances for two months, with decided emaciation. Sudden, severe colic. After several days a diagnosis of gall-stones by Oppolzer. The attacks were repeated for three or four weeks, when eighteen gall-stones were discharged. Three days later another intense attack with vomiting; prognosis grave. On the following day a slough discharged from the bowels. Recovery in three weeks, and the patient well seventeen years later. Rokitansky examined the slough and recognized it as the sequestrated pancreas.—Trafoyer, 1862. v. Chiari. *Wiener med. Woch.*, 1880, xxx. 139, 164.

Case LVIII.—Female, aged fifty-four. Corpulent, alcoholic. For several years gastric pains and occasional vomiting after meals. Irregular defecation. Stools often black. A few attacks of jaundice. Violent pains in region of stomach. Slight jaundice and fever. Swollen abdomen, painful epigastrium, nothing abnormal on palpation or percussion. Bedsore in the course of three weeks. Acute parotitis in the fourth week. In the last weeks failing appetite, increasing debility. Death after a short agony, the illness lasting seven weeks. Pancreas cylindrical, brownish-black, shreddy, and friable. It lay in the omental cavity, which formed a spacious pus-cavity, the walls densely fibrous with purulent infiltrations of the innermost layers. The liquid contents an offensive black fluid. A round ulcer of the stomach opened into the cavity; there was also a second opening between the two, and five openings into the jejunum. There was a thrombus in the splenic vein, and necrosis of fat-tissue.—Chiari. *Wiener med. Woch.*, 1876, xxvi. 291.

Case LIX.—Male, aged thirty-eight. Biliary colic a year ago. Slight, nocturnal abdominal pain for ten days, not interfering with occupation. It then became more severe, with sensation of twisting in left gastric region. On the fourteenth day suddenly awoke with persistent vomiting, followed by a dejection. Violent gastric colic. Soon anxiety, collapse, the epigastrium swollen, tense, sensitive. For a few days signs of intestinal obstruction, the abdomen swollen, the epigastrium sensitive. No fever. After repeated enemata an offensive stool and improvement. At the end of a fortnight a sudden febrile attack lasting three days, with symptoms of stenosis. After a fortnight a slough was discharged from the bowels. Recovery in five weeks, the entire illness lasting some twelve weeks. The slough proved to be the larger part of a gangrenous pancreas.—Chiari. *Wiener med. Woch.*, 1880, xxx. 142.

Case LX.—Female, aged forty-six. Strongly built, abundant fat-tissue; often suffered from cramps of the stomach. Severe abdominal pains for some days, frequent vomiting. Signs of a general peritonitis. Slight jaundice. After a chill, copious, black, offensive vomit, which continued till death. Duration of disease some three weeks. Pancreas dark brown, friable, lying attached only by a few rotten, fibrous threads in the omental cavity. The latter contained also abundant, ichorous, bloody fluid, and communicated with the duodenum and transverse meso-colon. Purulent infiltrations of the mesentery. Necrosis of fat-tissue. Numerous calculi in the gall-bladder. General peritonitis. The microscope showed merely remains of the pancreatic acini, but no evidence of hemorrhage.—Chiari. Loc. cit., 139.

Case LXI.—Female, aged twenty-seven. Typical case of diabetes. A year in the hospital under treatment. No particulars given. Head of the pancreas not abnormal, formed the right pole of an ovoid cyst, the wall of which arose immediately from the thickened and fibrous capsule, which is intimately connected with the posterior wall of the stomach and with a small part of the colon. The contents are 300 grammes of opaque fluid surrounding the tail of the pancreas, the tip floating free. The pancreas thus situated is flabby, macerated, and impregnated with large hæmatoidin crystals and acicular, orange crystals.—Israel. *Virchow's Arch.*, 1881, lxxxiii. 184.

Case LXII.—Female, adult. Well till within four months. In this time has had discomfort at the pit of the stomach and debility, but is able to be about. Sudden, severe epigastric pain, with vomiting of a copious, dark green, viscid fluid. Frequent stools resembling the vomit. Patient sleepless, temperature normal. Death in five days. Pancreas large, firmly adherent to adjacent parts, which were infiltrated with a discolored purulent fluid. The entire gland transformed into a dark, slate-colored, stinking mass, to within three centimetres of its attachment to the intestine, where it was sharply defined from the remaining more normal portion. Splenic vein contained a soft dark thrombus where it was in contact with the pancreas.—Whitney. *Boston Med. and Surg. Journ.*, 1881, cv. 593.

Case LXIII.—Female, aged fifty-seven. Eight weeks ago, violent pains, without obvious cause, constipation, speedy improvement. Three weeks ago, constipation again. For three days no dejection. Now, frequent,

[1] Hist. Anat. des Inflam., 1826, ii. 239.

green vomit, great prostration, marked swelling of left half of abdomen. Behind and below the dilated stomach a fluctuating tumor, immovable, size of a child's head. Laparotomy. Death in collapse after six hours. Pancreas necrotic, from which arose the suspected cyst, which was an abscess between the stomach and small omentum. The contents were an opaque, stinking fluid. There was fecal accumulation from pressure of the cyst upon the upper part of the small intestine which was adherent to it.—Rosenbach. *Cblatt. f. Chirurgie*, 1882, ix. Beil. 66.

CASE LXIV.—Female, aged thirty-two. Strong, abundant fat-tissue. Four weeks ago, sudden vomit, at first slimy, then bloody and greenish. Soon violent pains in the loins and back, fever, headache. Scanty, high-colored urine. Abdomen then began to swell. Now no fever, irregular pulse, clear intelligence, dyspnœa, abdominal pain, debility, abundant stools, albuminuria. For a few days temperature from 100° F. to 102° F., rarely normal and subnormal. Great abdominal distention, flanks dull. Five days later sudden death, preceded by increased dyspnœa. Pancreas, often appearing as if macerated, lay free, with the exception of its duodenal attachment, in a cavity, holding about a litre, which was exposed by separating the fibrous and fibrinous adhesions of the root of the mesentery to the transverse meso-colon. It lay on both sides of the spine, extending to the pelvis, behind the cæcum and descending colon, and, in places, separated the muscles which were covered with shreds. The contents were a greasy, grayish-yellow detritus, mixed with larger fragments, some nearly as large as a hen's egg. These appeared to have been shelled out of cavities, the walls of which were in part of an iron-rust color, in part dark brown, in part infiltrated with blood. The wall surrounding this necrosed fat was opaque, grayish-yellow or yellowish-white, narrow and sharply defined, without purulent infiltration. The mesentery contained numerous large and small, opaque-white patches, with, here and there, rust-colored edges. These had a centre of necrotic fat-tissue. There were recent pleurisy, a fatty heart, thrombosis of the left femoral vein, and embolism of the pulmonary artery.—Balser. *Virchow's Arch.*, 1882, xc. 523.

CASE LXV.—Male, aged twenty-two. Strong, abundant fat-tissue. A week ago, immediately after turning a handspring, felt a sharp pain in the lower abdomen. In the night, sudden, severe cramp of stomach, vomiting, chills, and sweating. A few hours later, collapsed, anxious, restless. Severe abdominal cramps; circumscribed tenderness near navel. Temperature normal. On the following day fever and diarrhœa. After temporary improvement lasting a week, there were persistent diarrhœa, pains, and tenderness of the navel, slight fever and considerable tympany just before death, on the fifteenth day. Site of the pancreas occupied by a black, shreddy, sloughy, soft, gangrenous mass; these characteristics most marked in the central region of the organ. The head and tail were represented by a central portion of a black, sloughy mass in which no trace of gland-structure was to be made out, which was encapsulated by the external portion. On raising the transverse colon a ragged blackish mass appeared, from a rent in which flowed a large quantity of thin, chocolate-colored fluid, also two or three soft clots size of an egg. No cardiac source of embolism. Acute peritonitis.—Prince and Gannett. *Boston Med. and Surg. Journ.*, 1882, cvii. 28.

CASE LXVI.—Female, aged forty. Umbilical hernia for two years. Irreducible for two weeks, with pain and swelling. Abundant fat-tissue. On the day after entering hospital for treatment of hernia, vomited breakfast; severe paroxysms of colic; small, flickering pulse. Nausea and bilious vomiting persisted on the next day; the face became anxious and pinched; the pulse 100, at times indistinguishable; the temperature normal. The pulse became 140, temp. 100.8° F., and she became pale, gasping and comatose, and died on the fourth day. Hemorrhagic infiltration and gangrene of the pancreas. Circumscribed peritonitis, gangrenous phrenitis. Acute pleurisy and pericarditis. Thrombosis of the splenic vein.—Homans and Gannett. Boston City Hospital MSS. Records, 1883.

CASE LXVII.—Male, aged forty-nine. In past three years, three attacks of jaundice, bilious vomit, severe pains and abdominal tenderness, most marked near xiphoid cartilage. After dinner burning in stomach, nausea, much abdominal pain. On the following day jaundice, bilious vomiting. The latter persisted for several days with frequent belching, and loose dejections. The abdomen became resonant except in the right flank, generally tender; temperature on the eighth day 100.8° F. Pulse and respiration rapid. On the tenth day he fell to the floor while trying to leave the bed, and soon died comatose. Hemorrhagic infiltration, necrosis, and sequestration of the pancreas, and multiple, disseminated necrosis of the subperitoneal fat-tissue.—Whittier and Fitz. Mass. Genl. Hospital MSS. Records, 1884.

CASE LXVIII.—Male, aged forty-two. For four years repeated attacks of vomiting, without colic, followed by jaundice lasting four or five days. During first five days paroxysms of abdominal pain, swelling of abdomen, vomiting, jaundice, two to three daily chills, fever; on the sixth day temp. 100.4°. Some green vomit. Pulse hardly quickened, no albuminuria. Abdomen inordinately distended and resistant, very sensitive, dense, and dull in left upper quadrant. Sudden collapse on the ninth day. Death on the thirteenth day. Tail and part of the body of the pancreas very soft, gray, discolored, infiltrated with a thin, ichorous fluid; the peripancreatic tissue partly purulent, partly ichorous. Spleen greatly enlarged, soft, splenic vein contains a soft, partly puriform thrombus, extending to the portal vein. Acute leptomeningitis.—Mader. *Ber. d. k.k. Kranhenhaus.* Rud-Stuft in Wien, 1884.

CASE LXIX.—Male, aged thirty-six. Powerful frame, abundant fat. In habit of drinking. From early youth attacks of abdominal pain, without constipation. A year ago the attacks became more frequent. After a hard day's work intense pain in mid-abdomen. In the course of three days no dejection. Temp. 100.4° F. Slight jaundice then appeared. There was a feeling of abdominal tension, although the abdomen was tympanitic and not remarkably distended. The nausea became lessened, the jaundice increased, the abdomen more distended, there was no excess of indican in the urine. On the seventh day the abdomen tended to retract except in the left upper part, where it was very sensitive. Laparotomy. The abdominal pain remained severe after the operation; there was no stool; and death, preceded by collapse, took place on the tenth day. Pancreas dense, nodular, with hemorrhagic coating; acini dull, yellowish-gray. Dry, hemorrhagic masses with yellow spots of softening. In the head are fatty softening and a hemorrhagic infiltration extending into the surrounding tissue. At the back of the pancreas a narrow line of hemorrhagic and necrotic tissue, beneath it the duct with necrotic wall. Left kidney and supra-renal capsule showed extensive, subperitoneal hemorrhage. The microscopic examination of the pancreas showed necrosis of the fat tissue with hemorrhagic processes in the tissue surrounding the fat lobules.—Gerhardi. *Virchow's Arch.*, 1886, cvi. 310.

CASE LXX.—Male, aged fifty-nine. Weight two hundred pounds. Strong and healthy. Two weeks ago thrown from carriage, but did not consider himself injured. The attack began with intense pain in the left abdomen, without fever; apparent improvement for three days, then labored and jerking breathing, rapid, extreme exhaustion, and death in ten days after the onset of the pain. The pancreas and mesentery showed a gangrenous parapan-

creatitis and necrosis of the mesenteric fat-tissue.—Foster and Fitz. MSS. Records, 1887.

The records of the Boston City Hospital give the following details concerning Case LXVI.

The patient, married, forty years old, with abundant fat-tissue, strained herself two years before her death, while lifting a heavy tub. There were immediate umbilical pain and swelling, but she was not compelled to give up work. Until two weeks before she entered the hospital she was able to replace the umbilical hernia. Since then the swelling and pain have increased.

On the day following her admission as patient, she vomited after breakfast, and was seized with a severe paroxysm of colic. The pulse became small and flickering. On the following day there were nausea and bilious vomiting, the pulse remained very weak, at times not perceptible, and the face was pinched and anxious. The temperature was not elevated. On the third day the vomiting had ceased, but the face was flushed, the temperature 100.8° F., and the pulse 144. She became comatose the next day, and died. Pallor, gasping respiration, a temperature of 100.8° F. and a pulse of 124 were recorded. The coils of intestine in the immediate vicinity of the pancreas were united together, and to the diaphragm, by recent fibrinous adhesions. On removing these the pancreas was found to be doubled in size, of a dark red color, and of a somewhat diminished density. On section, the tail was of a nearly uniform red color, soft, and its tip was shreddy. The duodenal portion was of normal density and of a mottled red and gray color.

The splenic vein was filled with a reddish thrombus, in places softened at the centre. The under surface of the diaphragm presented a dirty, grayish-white, shreddy appearance. A section through the diaphragm showed it to be four times as thick as usual, and to contain numerous small collections of dirty gray, puriform fluid. The diaphragmatic tissue was quite shreddy. There were an acute fibrinous pericarditis and a sero-fibrinous pleurisy. The umbilical hernia was omental and adherent.

Case LXVII. has the following record. The patient was an Irish laborer, forty-nine years of age, abundant fat-tissue.

In the past three years he had had three attacks of jaundice, with bilious vomiting, severe pain, and tenderness over the xiphoid cartilage. He had suffered also from severe paroxysms of abdominal pain, and had been told by a physician during the past winter that he had passed a gall-stone.

After dinner he suffered from a burning sensation in the stomach, followed by nausea and severe abdominal pain, not paroxysmal, but increased on motion. He became jaundiced on the next day and vomited a dark green fluid, and considerable mucus. For the subsequent three days the vomiting persisted, and there were frequent gaseous and bitter eructations, also several loose, dark green dejections.

He entered the hospital on the fifth day. The jaundice was conspicuous, the abdomen was resonant, except in the right flank, and sensitive. The pulse was 100 and the temperature rose abruptly from 97.4° F. to 100.8° F. During the subsequent four days the diarrhœa persisted. The urine contained a trace of albumin and a variety of casts. The pulse varied from 120 to 150, the respirations were very rapid, and the temperature remained moderately elevated.

On the eighth day he dressed himself, but did not seem conscious of his actions. He became mildly delirious on the following day, and while trying to escape from the ward, fell forward, was temporarily unconscious, and his pulse could not be counted. The temperature became subnormal, but arose to 100° F. in the evening. On the tenth day, while trying to leave the bed, he fell to the floor, his pulse became weaker and more rapid, his breathing resembled the Cheyne-Stokes rhythm, and he died comatose.

The posterior wall of the stomach and the upper part of the mesentery were united by fibrinous adhesions to the pancreas, which lay in a cavity, within a spongy meshwork, infiltrated with dirty green fluid. The pancreas was dark brown, dry, and firm. On section the lobules were indistinct and the surface granular. Numerous opaque-white patches were seen, resembling those to be described in connection with the abdominal fat-tissue. The splenic vein contained a mixed thrombus, four inches long and one-half the thickness of the little finger, and continued into several of the pancreatic branches. The spleen was soft and small. The liver was moderately granular and fatty. The gall-bladder was contracted about several calculi, the largest nearly the size of the end of the thumb, and projecting into the cystic duct. The walls were thick and tough, the mucous membrane thin, and streaked with opaque-white lines. The cystic and common ducts were dilated.

The superitoneal fat-tissue of the abdominal wall, mesentery, omentum, and perinephritic region contained numerous superficial and deep-seated small, circumscribed, rounded, opaque-white, and saffron-colored patches. In general, they were elongated, measuring an inch by a quarter of an inch. Rarely they were nodular, as large as a filbert, and on section contained dark brown, discolored centres. Sections of the frozen fat-tissue showed numerous cavities containing a shreddy tissue infiltrated with opaque-pink fluid of creamy consistency. Microscopical examination of the fresh specimens showed numerous leucocytes and large, round cells, with granular detritus, opaque-white specks, and bundles of small, acicular or rod-like crystals.

There was nothing abnormal in the appearance of the stomach or intestines.

The microscopic examination of the hardened pancreas shows a small quantity of interlobular fat tissue. In this are numerous islets of necrosis, the appearances being essentially the same as those found in the parapancreatic fat-tissue.

The larger ducts are filled with clumps of coherent, detached, cylindrical epithelium with distinctly stained nuclei.

The gland-cells in certain parts, especially in the immediate vicinity of the necrotic fat-tissue, are swollen, granular, confluent, and without evident nuclei. The outlines of the acini are irregular or indistinct. Certain of the lobules present a diffused infiltration of round cells. Many of the acini show a central accumulation of homogeneous, hyaline material, with corresponding flattening of the gland-cells.

Sections of the subperitoneal and parapancreatic fat-tissue present numerous patches, varying in extent and shape, all more or less rounded, oblong, or leaf-like. They are sharply defined by a limiting zone, varying in width, of small, round-celled infiltration between the fat-cells. Next this cellular layer is often found a narrow, orange-colored streak, in which are frequent granules and round clumps of small, orange-colored acicular crystals. Within the patch the outlines of the fat-cells are often distinct over considerable areas, but elsewhere are almost wholly, if not entirely, obliterated by the clusters of large and long acicular crystals and granular material. These crystals were isolated, dissolved, and recrystallized by Dr. Harrington, assistant in chemistry at the Harvard Medical School, and are pronounced by him to be identical with those obtained from ordinary tallow.

In addition to the crystals and granules, bacteria were found, both as circumscribed colonies within, and as diffused accumulations without the patches.

In the fat-tissue surrounding the patches of necrosis are occasional hemorrhagic spots with distinct outlines of

red blood-corpuscles. Small and irregular patches of leucocytes, without intercellular substance, are to be seen, occupying more space than that of several fat-cells.

Occasionally, elongated bands are found considerably wider than any visible bloodvessels. They are composed of agglomerated round-cells with solitary, larger corpuscles containing granular pigment. At each side of the central streak are numerous isolated, round and larger, flat, polygonal cells with large nuclei. These, in turn, are defined externally by a margin of clustered leucocytes. Arteries and veins are free from obvious changes.

The following record of Case LXX. is given as fully as possible. It is to be regretted that neither the specimen nor a detailed description of the pancreas was preserved. A gentleman, fifty-fine years of age, temperate, strong, and healthy, weighing 200 pounds, was thrown from his carriage, but did not consider himself injured. Four days later he was seized with intense pain in the left abdomen, associated with nausea and vomiting. At the outset the pulse was 80, and the respiration 24. There was no fever at any time. After a few days the pain and tenderness were relieved. From the outset extreme exhaustion was a conspicuous symptom. Eventually rapid and labored breathing came on, and the patient died on the tenth day.

A memorandum on the back of the letter accompanying the specimens and giving the clinical details, states that the conspicuous lesions were a gangrenous peripancreatitis and necrosis of the mesenteric fat-tissue. From the lack of further details the question might be raised as to the exact method of origin of the gangrene and necrosis. At the time I was satisfied that the case was analogous to that which immediately precedes, viz., Case LXVII.

Of these fifteen cases seven were males and eight females. Their ages were as follows:

	15

They were from all walks and conditions of life. Five were very fat, one was decidedly lean; five were strong and two of them were addicted to alcoholic drinks.

Eight of these patients had been subject to earlier, more or less repeated, attacks of digestive disturbance. These were always attended with pain, usually referred to the region of the stomach, or stated to be biliary colic. They were frequently accompanied with vomiting, and in one-third of the number with jaundice. Constipation or irregular defecation might occur, and in the latter case the stools were black.

At first sight, the etiological importance of perforating gastric ulcer and of gall-stones seems immediate, as illustrated by Cases LVII., LVIII., LXVII.

The comparison of these cases with others in the series would suggest that these affections were more important from the associated inflammation of the mucous membrane, with its opportunity of extension into the pancreatic duct, than from the actual or possible perforation of the biliary or digestive canal.

A traumatic cause for the fatal illness was possible in two instances.

In the one the patient was seized with a sudden pain in the lower abdomen, while turning a handspring, a week before the fatal illness. In the other the patient was thrown from his carriage five days previous. One person was seized with an attack while under treatment for an umbilical hernia of two years' duration. A mid-day meal and a hard day's work were each the immediate antecedent of the attack.

The illness usually, in four-fifths of the cases began suddenly, without definite cause, with abdominal pain. This was rarely slight, but often intense or severe. It was referred to the stomach, left hypochondrium, navel, mid-abdomen, and left loin and back. The pain might be constant or paroxysmal like a biliary colic, and a diagnosis of gall-stones was made in one instance.

Vomiting was the next symptom of importance, being recorded in three-fifths of the cases. Partly digested food was ejected, or a viscid or slimy fluid, often green, sometimes black or bloody. Constipation was, at times, so conspicuous that, in connection with the other symptoms, a diagnosis of intestinal obstruction was made in three cases and laparotomy performed in two. On the contrary, frequent, bilious stools might occur.

The urine might contain albumin and casts. In one case an excess of indican was repeatedly sought for, in vain.

Jaundice, usually slight, occurred after a few days in one-fifth of the cases.

Chills were occasional, sometimes at the onset, and fever was frequent after a few days. The temperature was likely to be low, in the vicinity of 100° F., although it might be as high as 104° F. There might be no conspicuous f ver throughout the course of the disease.

Swelling of the abdomen was present in one-half of the cases, usually occurring as a late symptom.

It might be slight or enormous, general, or limited to the epigastrium, or to the left half where a fluctuating tumor was to be recognized. The abdominal swelling was usually tympanitic, although dulness might be present in the flanks. The spleen was palpable in a single instance, and the parotid became acutely swollen in another case.

As the disease ran its course, weakness became apparent. Vomiting, perhaps diarrhœa, and abdominal pain were noticeable, suggestions of peritonitis were frequent, and symptoms of collapse were likely to take place, being followed more or less rapidly by death, which occurred as follows:

On the 4th day in	1 case.
" 5th "	1 "
" 10th "	3 cases.
" 13th "	1 case.
" 15th "	1 "
" 18th "	1 "
At the end of 3 weeks in	1 "
5 "	1 "
7 "	1 "
8 "	1 "
Not stated in	1 "

Two patients recovered with the discharge of a slough through the bowel, one at the end of eight weeks. One of these patients was living seventeen years later.

The diagnosis lay between intestinal obstruction, biliary calculi, and peritonitis.

The appearance of the pancreas varied according to the duration of the disease. About the fourth day[1] the pancreas may be doubled in size, dark-red, and of somewhat diminished consistency. It may be red, on section, or mottled red and gray. The tip may be shreddy, or the entire gland may be transformed into a dark, slaty-colored, stinking mass. The adjacent parts may be infiltrated with a discolored, purulent fluid, or the coils of intestine near the pancreas may be united by recent adhesions together and to the under surface of the diaphragm.

The latter may show a dirty, grayish-white, shreddy appearance, and its thickened substance may contain small collections of dirty gray puriform fluid, the tissue itself being quite shreddy.

On the tenth day[2] the pancreas may be dark brown, dry, firm. It may have a hemorrhagic coating or lie in a sponge-like meshwork infiltrated with dirty green fluid. On section, there may be dry, hemorrhagic masses, with yellow spots of softening, or the lobules may be indistinct, with intervening, opaque-white patches like those to be found in the neighboring fat-tissue. The hemorrhagic infiltration may extend beyond the gland. The wall of the duct and the overlying tissue may be necrotic and hemorrhagic. The perinephritic fat and that near the supra-renal capsule may contain extensive hemorrhages.

Toward the end of the second week[3] the pancreas may be a soft, black, shreddy, sloughy, gangrenous mass, the central part being encapsulated by the peripheral portion. Between the pancreas and the transverse colon may be a large quantity of chocolate-like fluid and large, bluish-black clots. Or the tail and a part of the body may be soft, gray, discolored and infiltrated with a thin, ichorous fluid while the para-pancreatic tissue is partly purulent and partly ichorous.

A few days later[4] the pancreas may be a thin, flabby, friable, grayish band, lying in a cavity behind the stomach and attached by a few shreds to the omental wall. The cavity may contain ichorous fluid and communicate with the stomach by several openings with frayed edges.

At the end of three weeks[5] the dark-brown pancreas may lie nearly free in the omental cavity, attached only by a few rotten shreds of fibrous tissue. The cavity may contain abundant ichorous, bloody fluid and communicate with the duodenum. During the fourth and fifth weeks the pancreas may be discharged as a slough from the bowels.

In the fifth week[6] the pancreas may lie free, as if macerated, in a cavity extending behind the cæcum and descending colon, on both sides of the spine, as far as the pelvis. The contents may also be a greasy, grayish-yellow detritus, with fragments of necrotic fat-tissue nearly as large as hen's eggs. The latter are apparently sequestrated from spaces with walls of a dark-brown or iron-rust color.

At the end of seven weeks[7] the pancreas may be transformed into a cylindrical, shreddy mass of brownish-black, friable tissue. This may lie in the omental cavity, which is filled with offensive, black fluid and communicates with the stomach and jejunum.

Thrombosis of the splenic vein frequently accompanies the pancreatic lesion and is usually parietal. The thrombus in the early stages is soft and dark red, or it may be of a reddish-gray color. It has been found partly puriform, and extending to the portal vein, at the end of the second week.

A little later it has been found completely obstructing.

The spleen may be soft, and is either large or small. Disseminated fat-necroses are often seen.

From the frequent mention of the position of the pancreas in the omental cavity filled with ichorous pus, it is evident that an acute peritonitis with liquid exudation is a frequent, if not the usual, occurrence. The pus may be prevented from entering the general peritoneal cavity by adhesive obliteration of the foramen of Winslow.

Peritoneal adhesions between coils of intestine are not infrequent, especially in the vicinity of the root of the mesentery. A general, suppurative peritonitis is of comparatively rare occurrence.

The inflammatory process may be extended to the pleural and pericardial cavities, and an acute lepto-meningitis has been found on the thirteenth day. At a late stage of the disease, death may result from pulmonary embolism.

The possibility of an arrest of the processes resulting in pancreatic necrosis and parapancreatitis is evident from Case LX. Although the patient died of diabetes, the symptoms of which lasted at least a year, the tail of the pancreas was flabby and macerated, and its tip lay free in a cyst arising immediately from the pancreatic capsule.

It is obvious from the anatomical appearances in this group of cases of gangrenous pancreatitis, para- and peri-pancreatitis, that the lesions are associated with a hemorrhagic pancreatitis in a considerable number of cases. In at least one-half there is mention of hemorrhage into the pancreas or of such discoloration as to suggest a hemorrhage.[1]

A comparison of the clinical history of this series of cases with that of hemorrhagic pancreatitis will show a strong resemblance in predisposing causes and in the nature of the symptoms. These are essentially identical in nearly all. In many of the remaining cases the symptoms are those which would favor the diagnosis of a hemorrhagic pancreatitis.

In any event they represent the termination of acute pancreatitis in gangrene, with an extension of the process to the contiguous tissue.

Viewing the subject from the anatomical side it is evident that cases of hemorrhagic pancreatitis may terminate fatally within a few days, either with or without necrosis of the gland and parapancreatic fat-tissue. They may also prove fatal in from one to four weeks, in consequence of an extension of the disease to the para- and peri- pancreatic tissues, with gangrene of the parts concerned.

(To be concluded.)

ORIGINAL ARTICLES.

THE TREATMENT OF ACUTE AND SUBACUTE NEPHRITIS.[1]

BY FRANCIS DELAFIELD, M.D.,

PROFESSOR OF PATHOLOGY AND PRACTICAL MEDICINE IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

ALTHOUGH I am to bring forward for your consideration this evening the treatment of acute and subacute nephritis, I must acknowledge at the outset that I have no new drug to propose, no new plan of treatment to advocate. Rather is it my object to determine, if possible, how plans of treatment and drugs already employed are to be intelligently applied in individual cases of the disease. For it is of importance not only that patients should be cured of their disease, but that this cure should be effected as speedily and as comfortably as possible; or, if the disease is an incurable one, that life and the capacity for labor and for enjoyment should be prolonged to the utmost.

To give an idea of the methods of treatment ordinarily employed, it will be sufficient to quote shortly from a French, a German, and an American author.

Labadie-Lagrave in the *Nouveau Dictionnaire de Médecine et de Chirugie*, xxx. p. 761, says:

"In acute nephritis the activity of the urinary secretion is the measure of the situation of the patient. The principal indication is to favor diuresis. Ordinary diuretics, including digitalis, are dangerous, but in milk we have at once a diuretic and a food. To make up for the insufficient action of the kidneys we employ warm baths and drastic cathartics. The dropsy does not require special treatment. Vomiting, if not excessive, is to be regarded as salutary. In the uræmic attacks we employ bleeding, chloroform, and chloral hydrate. In uræmic coma we advise inhalations of oxygen gas with the administration of caffeine.

As soon as convalescence is established the patient should return to a solid diet and take iron and tonics."

Strümpell, *Practice of Medicine*, English translation, p. 794, says:

"There is no way of directly affecting the inflammation of the kidneys. The chief object of treatment is to prevent the injurious results of the defective elimination of the solid and fluid constituents of the urine. To effect this object the patient should be kept in bed, on a milk diet; and the skin by means of diaphoretics, the intestines by means of cathartics, should be made to act vicariously for the kidneys. Dropsy is to be treated by sweating, cathartics, diuretics, and puncturing the skin or the serous cavities. Vomiting and diarrhœa are to be regarded as salutary. Uræmic attacks are to be treated with cathartics, chloroform, sometimes morphine."

Flint, *Practice of Medicine*, p. 872, says:

"The objects of treatment are: 1. Diminution of the intensity of the renal inflammation, promotion of resolution, and restoration of the excretory functions of the kidneys. 2. Diminution or removal of dropsical effusions. 3. Elimination of urea through the skin and gastro-intestinal mucous membrane if uræmia exist or be threatened. The patients are to be kept in bed and on a fluid diet. To diminish the nephritis dry cups or hot fomentations are to be applied over the kidneys and saline laxatives given. For the dropsy we use cathartics, the saline diuretics, and digatalis; for the elimination of urea, cathartics, pilocarpine, hot-air baths, bitartrate of potash, infusion of digatalis, decoction of broom, or plain water; for coma and convulsions, venesection, chloroform, chloral hydrate; during convalescence a generous diet, exercise, and iron."

Most other authors take much the same view of the treatment; that its main object is to make up for the diminished quantity of urine by action on the skin and intestines; and that the principal danger of an acute nephritis is the accumulation of excrementitious substances in the blood.

Some authors, in addition, believe that they can rest the kidneys while they are inflamed, by producing diaphoresis or catharsis, and that such rest will diminish the severity of the nephritis.

Some think that by a sufficiently large ingestion of fluids the inflammatory products can be washed out of the kidneys; a procedure which seems to be analogous to the treatment of scouring the blood, which is practised by some eclectics.

Digitalis is regarded with apprehension by some, while others warmly advocate its use as a diuretic, or as a remedy for the febrile movement (Gerhardt).

Morphine in considerable doses is employed by some for the relief of uræmic attacks; in small doses by others to relieve vomiting and restlessness; while still others deprecate its use under any circumstances.

General bloodletting seems to be restricted by most to the nephritis of pregnancy, and to the very severe forms of the disease attended from the first with high temperatnre and cerebral symptoms.

The disposition at the present time to direct attention and treatment to the symptoms of the nephritis, rather than to the nephritis itself; to the dangers of a diminished excretion of urine, rather than to the bad effects of kidneys in a state of acute inflammation is so general and decided that it may be wholesome to look at the subject from the opposite point of view, and to direct attention not to the functions of the kidneys, but to the kidneys themselves.

In order to do this we must at once separate the cases of acute nephritis from those of subacute nephritis, the condition of the patients being altogether different.

I. ACUTE NEPHRITIS.

Most of the cases of acute nephritis which we meet with complicate scarlatina, diphtheria, or pregnancy. Less frequently the nephritis complicates one of the other infectious diseases or severe inflammations, or it is a primary lesion.

In all cases of acute nephritis one morbid change

[1] Read before the New York Academy of Medicine, March 7, 1889.

is constant—congestion and exudation from the bloodvessels. The exudate consists of blood-serum, white blood-cells, and red blood-cells, which escape for the most part into the tubes and are mixed with the urine, to a less extent into the stroma of the kidney. The principal part of the exudate is regularly serum, but in some cases the emigration of white blood-cells is considerable, and in some cases with a large emigration of white blood-cells the exudation of serum is but small. In addition to this constant change in the kidney, other lesions may or may not be added. There may be swelling and multiplication of the cells covering the tufts of the glomeruli. There may be degeneration and death of the renal epithelium. There may be a growth of the capsular cells of the glomeruli, compressing the tufts of vessels. There may be a growth of new connective tissue in the stroma of the kidneys.

According to the severity of the nephritis, symptoms of varying number and severity are presented by the patients.

In the very mild cases the only symptom is a diminution in the quantity of the urine, and the presence in it of the exudate from the kidneys—the albumin, casts, and red and white blood-cells.

In the more severe cases the same changes in the urine exist and there are added constitutional symptoms—fever, prostration, loss of appetite, nausea, vomiting, anæmia.

In the still more severe cases there are also headache, delirium, stupor, convulsions, labored heart action, hypertrophy of the left ventricle, a pulse of high tension, and dropsy.

In the cases in which the urine is suppressed for a number of days, the patients develop alternating stupor and delirium and pass into the typhoid state.

The regular duration of a fairly developed acute nephritis seems to be about four weeks. Its natural termination, whether with or without treatment, is in recovery. But the more severe cases may prove fatal; the cases in which there is from the first a growth of new connective tissue in the stroma, are likely to become chronic.

With a nephritis of such a character and attended with such symptoms, what are the indications for treatment?

In the very mild cases evidently no treatment is necessary, except to keep the patients in bed and on a fluid diet.

In the more severe cases it is often proper to interfere in order to secure greater comfort and safety for the patient.

The different conditions which may call for treatment are: The nephritis itself. It is to be remembered that, although the quantity of urine voided is small, its quality is good, for it contains a fair proportion of excrementitious solids to the ounce of fluid; that convulsions and coma belong to the early days of a nephritis with scanty urine, while prolonged anuria is accompanied rather with the typhoid state; that the excretion of urine must naturally relieve the congestion of the kidney, so that it is better for the kidney to perform its functions than to be at rest; that so long as the congestion of the kidneys persists the quantity of the urine will be diminished; that a considerable diminution in the quantity of urine continued for one or two weeks is often perfectly well borne.

It is not, therefore, necessary to pay attention to the diminished quantity of urine, and to try to make the skin or the intestines do the work of the kidneys; it is wiser, by relieving the congestion of these organs, to enable them to do their own work, knowing that the moment they begin to do this their congestion will be still further diminished, and that although the nephritis still continues, the excretion of urine may then be sufficient.

Fortunately, we have at our command means by which the congestion of the kidney can be diminished, not completely, it is true, but partly; not for any length of time, but for short periods.

These means are: Causing the blood to collect at the surface of the body by the application of heat to the entire skin; the use of dry cups, or wet cups, or heat over the lumbar region; the empirical use of calomel or sulphate of magnesia, in small doses, repeated at short intervals, until the bowels begin to move; the use of such drugs as will diminish the increased arterial tension. While the nephritis is still active, however, we do not expect that by the use of any means the urine will be brought up to its full normal quantity, but only that a sufficient quantity will be passed to insure the safety of the patient.

The febrile movement in an acute nephritis requires no treatment.

The prostration, loss of appetite, nausea, and vomiting only call for rest in bed and a fluid diet.

The anæmia ought unquestionably to be prevented or relieved, but while the nephritis is still active I know of no way in which this can certainly be done. When convalescence is established then the anæmia readily improves with the ordinary methods of treatment.

The cerebral symptoms are those to which most attention has been directed. There can be no question that they regularly accompany a contraction of the arteries with increased tension and labored action of the heart. No matter what views one may entertain as to the cause of this change in the circulation, I believe that treatment is best directed to the arteries themselves rather than to the uncertain cause of their contraction. Fortunately, we possess drugs which act promptly and efficiently for this purpose. Of these drugs, the most suitable are aconite, chloral hydrate, and opium, preferably given

in small doses and at regular intervals, so that their use can be continued for some time.

It is wise to watch the condition of the heart and arteries, and as soon as the condition of increased arterial tension is developed, not to wait for the manifestation of the cerebral symptoms, but to try to relieve it at once.

The treatment of a case of acute nephritis resolves itself, therefore, into the treatment of the nephritis itself, and of the contraction of the arteries which may accompany it. To carry out this treatment, I can, from experience, strongly recommend the following routine: The patient is put to bed and on a fluid diet; the entire skin is washed clean every day; for two successive days drachm doses of sulphate of magnesia are given every hour until one ounce has been taken, or the bowels begin to move; after this, the tincture of aconite is given in doses of one minim every hour.

Within a few days the albumin in the urine will have diminished, the pulse will be soft, the dropsy will have disappeared, but the patient will be anæmic. The milk is now gradually replaced by solid food, and iron and oxygen are given.

II. SUBACUTE NEPHRITIS.

The distinction between acute, subacute, and chronic inflammations is an arbitrary one, but yet often of real convenience. This is especially true of nephritis.

In acute nephritis, as we have seen, the inflammation is an acute and temporary one attended with congestion and exudation. The interference with the function of the kidney is only with the quantity of the urine; the urine that is produced is of good quality. The symptoms are due to the nephritis itself, and to the accompanying contraction of the arterial system.

In subacute nephritis, on the contrary, the inflammation is subacute and long continued; there is no congestion; the exudation is of the profuse, almost dropsical character that we meet with in other subacute inflammations, such as pleurisy with effusion; there are permanent changes in the stroma and glomeruli of the kidney. The interference with the functions of the kidney is not with the quantity of the urine—for this is often in excess—but with its quality, the proportion of solid matters steadily decreasing as the disease advances. The symptoms are largely due to the effect of the nephritis on the composition of the blood and the nutrition of the body. The anæmia, the dropsy, and the loss of strength are the prominent features of the disease. Contraction of the arteries is absent, or present at intervals. The cerebral symptoms are chronic rather than acute.

It may happen, however, that in the course of a subacute nephritis there will be exacerbations of the inflammation, during which the changes in the kidney and the symptoms are the same as those of an acute nephritis.

Subacute nephritis is especially common as a primary disease, and as a sequel of scarlatina and diphtheria.

The patients lose strength, they become anæmic; they suffer from nausea, vomiting, and diarrhœa; there may be inflammation of the retina; the arteries are for the most part relaxed, but may sometimes be contracted; the cerebral symptoms are more frequently chronic than acute, and dropsy is apt to be a marked symptom.

The urine may be somewhat diminished, but is often in excess. The specific gravity and quantity of solid matters excreted diminish as the disease progresses. The quantity of albumin mixed with the urine is considerable.

Some of the patients continue to get worse in every way, and die within one or two years.

Some of them exhibit some or all of the symptoms of the disease for weeks or months, then seem to be partly or completely well; and then again become ill, and so may go on for many years, sometimes better, sometimes worse.

In some of them, acute exacerbations of the inflammation may give for a time the symptoms of acute nephritis. A very few patients seem to recover permanently.

The conditions which require treatment in these patients are:

1. The subacute nephritis.
2. The changes in nutrition and in the composition of the blood.
3. The dropsy.
4. The condition of the arteries.
5. The cerebral symptoms.
6. The acute exacerbations of the inflammation.

For the nephritis itself the most efficient treatment is the residence of the patient in a suitable climate. The climate should be warm, and the particular locality selected should be one where the patient can lead an outdoor life.

If the patients remain in a cold climate, it will be necessary to confine them to the house for much of the time. Except during the exacerbations of the nephritis the patients should take as much of solid foods and of fats as they can digest. The excessive use of milk and of the mineral waters is to be avoided. It is possible that the use of opium or of the bichloride of mercury may favorably affect the nephritis.

The anæmia is a most important symptom. There is a diminution in the quantity of hæmoglobin and in the number of red blood-cells. The most efficient treatment for this is the internal use of iron and the inhalation of oxygen combined with massage and the relief of constipation. With this treatment in

many of the patients the improvement is satisfactory, but in some no such improvement takes place.

The dropsy may never be more than an inconvenience, or it may be the most distressing feature of the case. It is apt to reach its greatest development with low arterial tension and often with a large excretion of urine.

In some cases the treatment of the anæmia and the regulation of the diet will answer at the same time for the treatment of the dropsy. In other cases we must employ different means.

When a subacute nephritis has lasted for any length of time the quantity of urea excreted falls to six or seven grains, or even less, to the ounce. The patients ought therefore to pass daily seventy or more ounces of urine. If we wish to diminish the dropsy by increasing the quantity of urine, it is well not to increase the urine more than will be sufficient to enable the patient to excrete his five hundred grains of urea a day.

The quantity of fluids which the patients drink should be regulated, as far as possible, according to the quantity of urine passed; not allowing the former to exceed the latter.

In the extreme cases of dropsy we are obliged to purge, to sweat, to puncture the skin, to tap the serous cavities. But when these measures become necessary it means that the case is an unfavorable one.

The condition of the arteries and of the left ventricle of the heart should be watched throughout the disease. High arterial tension can often be controlled by nitro-glycerine, chloral hydrate, or opium. Low arterial tension can, theoretically, be heightened by digitalis or ergot, but I have found no advantage in doing this.

To avoid the cerebral symptoms we have constantly to watch the excretion of urea and the condition of the arteries. The quantity of urine should be kept large enough to make up for its diminished solid contents; increased arterial tension should be at once relieved.

The acute exacerbations of a subacute nephritis are to be managed in the same way as an attack of acute nephritis.

As I stated at the beginning of this paper, I am not able to offer any new plan of treatment. I have simply tried to show that some of the old plans may perhaps be more intelligently applied; and that, while symptoms have to be treated, that this may be done largely with direct reference to the nephritis. I trust that the discussion which will be elicited may be of more value than the paper itself.

HYSTERICAL VOMITING.

By HUBERT WORK, M.D. (Univ. Pa. '85),
of Fort Morgan, Colorado

Flora W., aged thirty-five, unmarried, previous health perfect and of good family history, was taken suddenly ill with nausea, vomiting, severe occipital pain, and slight febrile movement. These symptoms gradually subsided, except the fever, and disclosed developing typhoid fever, which presented the usual symptoms of this disease in a mild form, completing its course in four weeks, the temperature at no time rising above 103° F. Throughout this period of illness the patient never would admit feeling improved, nor express any opinion other than that she would never recover.

After four weeks my visits terminated, believing her practically recovered.

After ten days I was summoned and found my patient resignedly vomiting as though she was fulfilling a sacred duty, and was told that she had been doing so at intervals of two or three hours for twenty-four hours. Careful examination of all organs known to produce emesis, either directly or reflexly, gave negative results. Simple remedies were ordered without favorable result. A systematic course of treatment was then begun which embraced a trial of all remedies named as antiemetics in the materia medica, including cocaine; antipyrin by the bowel with blisters and ice externally.

The vomiting continued and became more frequent, so that after the fifth day there was a paroxysm of greater or less severity every hour, and many hours twice or thrice—nothing would remain on the stomach, lumps of ice were ejected before they had melted, accompanied with bile and water; this continued up to the tenth day, when streaks of blood appeared in the vomited matter. At no time during these ten days was there an increase of temperature—for two days it was subnormal; there was no pain in the head or headache, no strabismus, no abdominal tenderness; the bowels moved readily by rectal injections though scantily; no uterine displacement was detected, nor irritation from its appendages or tenderness of any organ. To state in her hearing that she was improving, or the absence of the nurse, or any fancied neglect, would be followed by a violent attack. Wearied by the importunities of the family "to do something" my stock of remedies and patience exhausted, I administered subcutaneously one-quarter grain of morphia with one two-hundredth of a grain of atropia with but little effect; in two hours this amount was repeated, with the result that the vomiting stopped, and was followed by a night's sleep, the first in four days. For four days the patient was kept stupefied by repeated small hypodermatics of morphia, when it was withdrawn and large doses of potassium bromide given by enema. Vomiting did not recur to any extent worthy of mention and on the fourth day after withdrawal of the morphia, food was given by the mouth and retained; after thirty-six hours nutrient enemata were abandoned and nourishment by the stomach persevered in exclusively. The patient, though mentally weak and suffering from

an occasional hysterical explosion, had no return of vomiting and the improvement rapidly terminated in perfect recovery.

ON CHRONIC HEADACHES OF FUNCTIONAL ORIGIN.

A Clinical and Etiological Study, based on Records of Two Hundred Cases.[1]

BY CHARLES L. DANA, M.D.,
PROFESSOR OF NERVOUS AND MENTAL DISEASES, NEW YORK POST-GRADUATE MEDICAL SCHOOL, NEW YORK.

THE trigeminal nerve is the most sensitive and highly differentiated of all the cutaneous nerves. From the beginning of mammalian life it has been at the front in the struggle for subsistence, and has received constantly an excess of stimulus over other sensory nerves, which has educated it to the very highest degree of delicacy and responsiveness. Spread over the face and cranium of man, it gives to him the best information that skin and muscles can anywhere afford, and is a source of protection and information, as well as of æsthetic gratification.

The penalty paid for this high degree of evolution of the trigeminus is its readiness to the assaults of disease, and its response to almost every pathological irritation. Headache and head-neuralgias are the most common of mortal afflictions, and may be symptomatic of almost any disease.

I intend, therefore, to speak now only of chronic and chronically recurring headaches of functional origin, but expressly excluding migraine.

What I have to say is based chiefly on an analysis of 200 cases of functional, non-migrainous headaches, whose records I have preserved.

FREQUENCY OF HEADACHE.—Sir Richard Owen estimated, from no definitely given data, that five per cent. of school children have headache.

Dr. G. E. Herman (*Medical Times and Gazette*, November 29, 1884) estimates that fourteen per cent. of school children have recurrent headache. Among 160 adults (67 women, 95 men) he found that two-thirds of the women (44) and one-fourth of the men (25) had recurrent headache.

Another observer found that among 334 women, 136 had headache at the molimen, and of these, 48 had migraine.

Among about 2000 cases of nervous disease, 200 (ten per cent.) came for chronic headache.

PATHOLOGY.—Headache is, strictly speaking, a form of neuralgia. It has a diffused character, owing to the part of the nerve involved.

The *seat of headache* is the external envelope of the skull and the dura mater; in rare cases only the skull being involved.

The *nerves affected* are, first, the trigeminal, which supplies the face and scalp as far back as a vertical line from the vertex, and the dura mater of the anterior three-fourths or more of the cranial cavity; second, the four upper cervical nerves which supply the posterior scalp and neck; and, third, sensory branches of the vagus which supply the posterior fossa of the skull.

The pia mater has vaso-motor but no sensory nerves, and the brain-substance is insensitive to pain until one strikes the prolongations of the sensory tracts in the brain axis and basal ganglia.

Sensory impulses from the face, scalp, or meninges flow along the trigeminus, cervical nerves, or vagus; they pass up through the sensory tracts in the medulla and pons, connect with nodal nuclei here and at the base of the brain, and finally impinge on those parts of the cerebral cortex which are known as the motor areas.

There are three types of head-pains, viz., headache, neuralgia, and migraine.

Headaches are caused, as a rule, by diffuse irritations located in or referred to the peripheral ends of this tract.

Neuralgias, on the other hand, are caused by irritations of the trunks of these nerves. The cortex itself may, perhaps, be the seat of a headache, but then it is a psychical pain and of the nature of a hallucination.

Migraine is a periodical neurosis in which there is a discharge of nerve force not only affecting the trigeminus, but often other cranial nerves as well as sympathetic fibres.

In chronic non-migrainous headaches, the periphery of the nerves supplying the dura mater is oftenest affected, and headaches are called by some intrinsic pains, while neuralgias are called extrinsic. In reflex, or, strictly speaking, transferred head pains the irritation is shunted off or diffused over from the original irritated nerve upon the central tracts of the trigeminus, or cervical or vagal nerves. The explanation of this is easy: The trigeminal nerve has central tracts which very easily awaken sensations in consciousness. The innumerable excitations of this nerve have broken a broad pathway to the cortical areas. On the other hand, the vagus branches to the stomach, for example, cannot by stimulation so easily arouse a conscious sensation; the nerve impulses started in it by an undigested bolus of food, therefore, pass up to the medulla, and then flowing over take the easier path to the cortex, viz., that of the first branch of the trigeminus, and the patient has frontal headache.

ETIOLOGY.—Chronic and recurrent headache is always a symptomatic trouble. We know of no such thing as essential or idiopathic headache aside from migraine. Its study, therefore, is naturally limited chiefly to the subject of etiology and treatment.

Predisposing causes. My patients represented a city population; many of them living in bad hy-

[1] Read at the meeting of the New York State Medical Society, February 6, 1889.

gienic conditions. The etiology of their troubles applies pretty correctly to headache in general, but no doubt somewhat different results would be reached in another country, a different climate, and in rural districts.

Sex. The males number 53, females 147. This gives a ratio of about 3 to 1 in favor of the female sex, and shows a greater preponderance relatively of headaches than of neuralgias in general, in which the ratio is as 5 to 3.

Headache belongs still more than neuralgia to woman.

Age. The following table shows the ages at which these headaches most prevail:

Age.	Male	Female.	Total.
5 to 10 years (inclusive)	10	14	24
10 to 15 " "	6	21	27
15 to 20 " "	3	29	32
20 to 25 " "	6	17	23
25 to 30 " "	4	11	15
30 to 35 " "	3	10	13
35 to 40 " "	2	14	16
40 to 45 " "	1	8	9
45 to 50 " "	6	1	7
50 to 55 " "	1	1	2
55 to 60 " "	1	4	5
60 to 65 " "	0	1	1
65 to 70 " "	1	0	1
Total	44	131	175

The headache ages are from 10 to 25 and 35 to 45; most cases occur between the ages of 8 and 25, especially in females. The number of headaches increases gradually from the period 5 to 10 years up to the period 15 to 20, then falls till the 35th year, and rises again till about the age of 40. Early childhood and declining age are practically exempt from chronic functional headaches.

The increase of headaches as middle life approaches is really greater than is apparent from the figures, since there are nearly one-third less persons living at the age of 35 to 45 than at the ages 10 to 20.

The exciting causes are:

1. Hæmic causes, in which impoverished or poisoned blood is brought to the brain, as in:
   - (*a*) Anæmia.
   - (*b*) Diathetic states:
     - gout,
     - rheumatism,
     - diabetes, etc.
   - (*c*) Infections:
     - malaria,
     - syphilis.
   - (*d*) Uræmia.
2. Toxic causes:
   - lead,
   - alcohol,
   - tobacco, etc.
3. Neuropathic states:
   - epilepsy,
   - neurasthenia,
   - chorea,
   - hysteria,
   - neuritis.
4. Reflex cause:
   - ocular,
   - naso-pharyngeal,
   - auditory,
   - dyspeptic,
   - sexual—uterine.
5. Organic disease.

This classification of headaches, based on the etiology, is very much like those usually given.[1] I have not included the so-called hyperæmic or congestive headache, however, because I have never met cases of this character which I did not think were in reality migraines, or the results of organic changes following sunstroke or meningitis.

Even the much quoted anæmic headache is rarely due to anæmia alone, as close observation will show.

The relative frequency of these different types was found to be approximately—

Hæmic and toxic forms	35 per cent.
Dyspeptic reflex	25 "
Other reflex	10 "
Neurotic	20 "
Organic	5 "

The great majority of chronic functional headaches are thus seen to be due to bad states of the blood—*i. e.*, toxæmias and auto-toxæmias—and next to disorders of the gastro-intestinal tract. Such disorders cause headaches which are partly reflex, but sometimes there is no doubt a toxic element due to absorption of ptomaines of great importance in them.

---

[1] The following classifications which have been made by different writers may be of interest:

Monneret:
- Neurotic.
- Congestive.
- Osseous.

Willis, Becquel:
- Accidental { essential. / symptomatic.
- Habitual { essential. / symptomatic.

Racle:
- Rheumatic.
- Congestive.
- Neuralgic.
- Anæmic.
- Neurotic.

Erb:
- Anæmic.
- Congestive.
- Toxic.
- Hysterical.
- Rheumatic.
- Reflex.
- Neurasthenic.

Of the typically reflex headaches the ocular rank first, while but few were due to nasal or aural irritation.

Next come the headaches of neurasthenia, epilepsy, and hysteria.

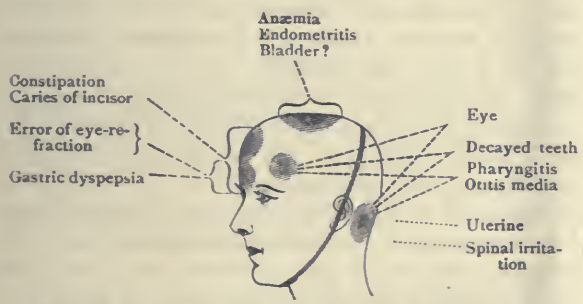
The toxic and diathetic headaches preponderate in the young, 27 out of 45 being under twenty years of age. The dyspeptic headaches belong to the age above twenty (19 out of 29), as do also the neurotic and organic head pains. On the other hand, ocular headache is more frequent in the young (66 per cent. under twenty).

In studying the etiology of headaches a question of much interest is that of the location and character of the pain.

Roughly speaking we have:

1. Frontal headaches.
2. Occipital headaches.
3. Parietal and temporal headaches.
4. Vertical headaches.
5. Diffuse headaches and various combinations of the above.

The most common form of headache is the frontal, next the fronto-occipital or diffuse, next the vertical, and then the occipital.



The significance of the location of the pain is a thing which has been studied with some care of late years.

In an article on "reflex pains" published in the *New York Medical Journal*, July 13, 1887, I tried to reach some conclusions on this point.

In making any general statements regarding this matter it would be safer and easier to speak of what does not cause a certain kind of headache than of what does.

For example, frontal headaches are rarely, if ever, due to uterine or pelvic irritation; neither are they due to aural or pharyngeal causes. Nor are they often due to troubles with the muscle-innervation of the eye. They rarely occur as pure frontal pains in the epileptic and neurotic.

Vertical headaches are rarely of toxic origin, and occipital headaches are not caused by anæmia or toxic conditions.

Modern studies of the subject of headache have brought into especial prominence the reflex factors in their causation. While the work of seeking for reflex causes has been probably overdone, yet much of practical and scientific interest has been elicited.

A brief review of this aspect of the etiology of headache may be in place here.

Ocular headaches. At the present time the eye is credited with giving rise to an immense number of head pains. Their location and character depend not only upon the pathological condition of the eye, but also upon the constitution and occupation of the patient. In my article already referred to, I gave some rules regarding the location and character of these headaches. They have been studied in still greater detail by Smidon. From my investigations, it seems to me that the most general rule which one can formulate is that headaches from refractive errors are usually frontal or orbital; those from muscular insufficiencies are more often occipital and cervical.

Naso-pharyngeal headaches. Nasal inflammations and hypertrophy cause dull frontal or diffuse headaches.

Enlargement of the pharyngeal tonsil may cause a dull, recurrent, occipital pain (Gradle, *Journ. Amer. Med. Association*). Follicular tonsillitis and hypertrophied tonsils may cause diffuse headaches; and in children obstruction of the Eustachian tubes may cause a diffuse headache.

Auricular headaches. Disease of the middle ear has been observed to cause temporal and occipital pains.

Gastric headaches, or *dyspeptic headaches*, when not accompanied with constipation, are often occipital, but sometimes frontal. Constipation and intestinal irritation usually cause a diffuse frontal headache.

Uterine and *ovarian headaches*, headaches from pelvic irritations, are almost always occipital and vertical. It is very rare to find pelvic irritations referred to the fifth nerve.

The view of Valleix, that most headaches were of uterine origin, is not all supported by modern observation.

A few words may be said regarding the character of some of the other kinds of head pains.

Neuropathic headaches. The typical hysterical headache or boring pain (*clavus*), is one rarely observed by me, and is often associated with spinal irritation. The neurasthenic headache is frontal and vertical, and is usually associated with a sensation of pressure or weight, and often with various cerebral paræsthesiæ. In spinal irritation, however, in its incipiency, or in mild types, there is a boring, occipital pain; while a still earlier symptom of a neurasthenic state is a neckache, or feeling of neck weariness, which the patient notices after trying to sit and hear a preacher or lecturer, or watch a play.

One type of the neurasthenic headache is frequently met with in brain-workers, coming on whenever the

mind or the eyes, or both, have been much overtaxed. Slight disorders of the eye or stomach, or a rheumatic or gouty tendency, are assisting factors in these headaches, and they are relieved by rest; or temporarily by antipyrin, an antirheumatic, or a bromide.

The *epileptic* headache is usually very severe, sharp, often vertical or occipital, not diffuse. It has more the character of a neuralgia.

The *organic headaches* are, as a rule, very characteristic. They are violent in character, and often associated with feelings of fulness and throbbing; nausea occurs frequently. They usually remit for a time, and then exacerbate. They are associated with other symptoms which usually make a diagnosis not difficult.

Syphilis causes a headache which is sometimes coronal or temporal, and is almost always partial, involving only a certain area in the skull. It is worse at night, and often comes on periodically, like a malarial headache.

Symptomatological Classification.—The term headache means a different thing with different persons, and in different types of the disease we have:

1. Pulsating, throbbing headache.
2. Dull, heavy headache.
3. Constrictive, squeezing, pressing headache.
4. Hot, burning, sore sensations.
5. Sharp boring pains.

The first form characterizes headaches with vasomotor disturbances and usually indicates migraine.

The second is a toxic, dyspeptic type.

The third is found in the neurotic and neurasthenic.

The fourth in rheumatic and anæmic cases.

The fifth in hysterical, neurotic, and epileptic cases.

Symptoms associated with Headache.—The symptoms oftenest associated with chronic and recurrent headaches are vertigo, somnolence, sensations of heat and pressure (cerebral paræsthesiæ), and nausea. Vertigo goes oftenest with headaches of dyspeptic origin; some of the so-called bilious headaches of early life develop later into attacks of vertigo; vertigo I found oftenest with frontal headaches.

Somnolence I found oftenest with anæmic and malarial headaches; it occurs also with syphilitic pains.

Nausea I found oftenest with occipital headaches.

Therapeutics.—The study of the etiology of chronic headaches is also a study of the therapeutic side; yet some general remarks may be made on this subject, approaching it from a different point of view.

The *treatment* of *headaches* of *young children*, for example, brings us into an almost special line of cases.

In the city of New York at least, these headaches are best treated as a rule by giving small doses of the iodide of iron or the citrate of iron and quinine. In school children headaches have often to be treated by removal from school, the use of tonics, change of diet, and the application of glasses suitable to any eye-defects that may be present. But glasses should be the last thing tried, unless the visual trouble is very marked. In some children arsenic acts well.

As to the *therapeutics of headaches of adults*: Headaches among brain-workers require, as a rule, a different class of remedies to those among muscle-workers. In the former class nervines like antipyrin, caffein, the bromides, act well, while attention to diet, exercise, and the eyes is especially required. Among the laboring classes, especially women, anæmia, malaria, syphilis, and rheumatic influences must often be attended to. There are sexual differences also to be borne in mind. In my experience, for example, antipyrin has been much oftener successful in men than in women. This may, however, be only a coincidence.

I shall conclude the subject of therapeutics with a few remarks on symptomatic remedies.

Among the best of these is muriate of ammonium in large doses, ʒss to ʒj, given in wafers.

In the headache of neurasthenia, I have found that gr. v of menthol in hot-water gives relief. In my wards at Bellevue Hospital a combination of menthol gr. v to x, and antifebrin gr. v to x, is often used. Phenacetin is also a good remedy. A practical point of importance in the use of antipyrin is the dosage. Often the best results are gotten by small doses frequently repeated.

The much advertised effervescent preparations for headache contain too small a dose of caffein or of bromide to be of the best service.

Of local applications a spray or lotion of aconitia; sheet lint soaked in twenty per cent. solution of menthol and wrapped on the head; solutions of cyanide of potash after the method of Trousseau; Rithet's tobacco and quinine snuff, are some of the measures indicated.

Every one meets now and then with cases of headache of obscure origin, obstinate in character and intractable to every kind of treatment. The use of iodide of potassium and of the strong galvanic current and static electricity has been of service to me in some such cases. The possibility of a diffuse neuritis as a cause of the pain in certain of these cases should be borne in mind.

50 West Forty-sixth Street, Feb. 4, 1889.

MEDICAL PROGRESS.

The Suspension Treatment of Locomotor Ataxia.—Dr. Paul Blocq has recently read a paper at the Société Médico-Pratique (*Rev. Gén. de Clinique*, Feb. 14, 1889) on the results of Dr. Motchonkowsky's treatment of locomotor ataxia by suspension, as carried out for the last few

months at the Salpêtrière. The treatment was suggested to Dr. Motchonkowsky, of Odessa, by observing the benefit which an ataxic patient, also suffering from spinal curvature, derived from the suspension required in applying a plaster jacket. On suspending other ataxics in a similar manner, he found that very marked improvement in the lightning pains and the motor incoördination followed, and vesical and sexual power was restored.

At the Salpêtrière fifteen patients have been submitted to 900 suspensions since last October, with marked benefit in many cases. The most usual signs of improvement were the reëstablishment of sexual function, the disappearance of bladder troubles, diminution and disappearance of the lightning pains, with improvement in motor coördination, so that patients who had only been able to walk with the help of an attendant on one side and a staff on the other, could leave the hospital after treatment without help of any kind.

Dr. Paul Blocq has also applied suspension with benefit in Friedreich's disease. The suspension was applied two or three times a week for periods varying from thirty seconds to three minutes each time. Improvement in walking began in the case of a girl, aged fourteen, in the second week of treatment. Later, a spoon could be carried to the mouth with the eyes closed, and she now learns the piano, writes with little tremulousness, can walk better, can stand with the eyes closed, and the catamenia have become established. The tendon reflexes are, however, still wanting, and scansion and nystagmus remain.

As Professor Charcot remarked, these results in a disease which has always been slowly progressive and almost invariably fatal, are worthy of attention. He suggests that the suspension may act by modifying the circulation of the spinal cord, or by stretching the nerves as they leave it. Whatever its *modus operandi* may be, it is certain that suspension is an agent of considerable power, since serious accidents have occasionally happened during the application of a Sayre's jacket, and it is, therefore, to be used with discretion and care.

We understand, also, that a number of patients suffering from various forms of chronic degeneration of the nervous system are being treated by suspension in various London hospitals. It is, of course, too early to form any definite opinion of the value of this treatment; but, so far, the results have been encouraging. A patient at present in St. Mary's Hospital was "suspended" on January 22d, and at intervals from that day, by Dr. de Watteville, physician in charge of the electro-therapeutical department, who has reported the case as progressing satisfactorily. The most apparent improvement consists in the increase of gait and equilibration, as manifested by the ease with which the patient can turn around when ordered to do so. Dr. Althaus informs us that he has found it beneficial in two cases of tabes; lightning pains in the one case, and in the other gastric crises, have ceased. In a case of severe paralysis agitans the tremor ceased for thirty-six hours after the first suspension.—*British Medical Journal*, February 23, 1889.

The *Berliner klin. Wochensch.*, No. 8, reports that the suspension treatment has been tried in the clinics of Professors Eulenberg and Mendel with equally favorable results, the suspensions, which took place three times a week, being at first of one minute's duration, increasing by half a minute up to three minutes. About twenty patients have thus been treated; and although, of course, the time is too short to announce any very positive results, two facts have been found to follow the treatment, viz.: 1. A certain number of patients have, immediately after the suspension, a readier and freer gait, less staggering, and complain less of lancinating pains (in some, also, improvement was noted in visual symptoms). 2. No ill effects have followed the practice. Our contemporary warns physicians and the public from hasty and exaggerated hopes in its efficacy.—*Lancet*, March 2, 1889.

The Etiology and Operative Treatment of Carcinoma of the Breast.—Dr. Fink, at a recent meeting of the Society of German Physicians, held at Prague, read a report upon the researches made by Dr. Redner, at Professor Gussenbauer's clinic, into the etiology and operative treatment of carcinoma of the breast. The principal points dwelt upon were:

Age.—Of those affected, 128 out of 194 were between 40 and 60 years, 28 between 20 and 40 years, and 38 between 60 and 80 years. Average age, 51½ years.

Function.—Of the 194 cases, 140 (72.1 per cent.) had borne children, and 122 of these 140 (62.8 per cent.) had nursed their own infants. It would thus seem that the repeated, as well as the prolonged, action of the mammary glands and the changes taking place therein, in consequence of such reaction, would favor the development of carcinoma.

Traumatism.—In 25 cases (12.7 per cent.) the causative connection between mechanical action on the mammary gland and the development of carcinoma was easily traced, as the tumor developed immediately after traumatic irritation had taken place.

Heredity could not be established.

The *treatment* consisted in amputation of the breast, which was performed on 153 patients. In nearly all the axillary space was cleaned out at the same time. The mortality ran up to 3.3 per cent., which must be taken as a most favorable result considering the unfavorable sanitary conditions of the wards, which contained, besides the patients operated upon, cases of phlegmon, erysipelas, and other wound-contagions. From experience the author concludes that in every case of removal of the breast for carcinoma the axillary space should be completely cleaned out, even though the axillary glands should seem free from infection.

Relapse was noticed in 97 cases, of which 90 died. In all these the process was far advanced, and the axillary glands implicated.

A *cure* was established in 29 cases (16 per cent. of those operated upon)—that is, three years have elapsed since the last operation, and no symptoms of reappearance have thus far been observed. Even those in whom a relapse occurred lived seven months longer when operated upon than did those who were left to die without surgical interference.—*Wiener med. Presse*, Feb. 17, 1889.

Treatment of Pityriasis Versicolor.—

℞.—Salicylic acid . . . . 3 parts
Precipitated sulphur . . . 10 "
Lanolin } . . . āā 50 "—M.
Vaseline }

To be applied to the scalp at night and washed off in the morning with soap and water. Continued for one

week, this treatment will almost always effect a cure.—*L'Union Médicale*, February 21, 1889.

On the Period for Surgical Interference in Acute Intestinal Obstruction.—DR. B. W. RICHARDSON recently read before the Medical Society of London a paper on this subject, confining his remarks to acute attacks. He summarized his conclusions as follows: 1. That in all cases of acute intestinal obstruction the use of milder measures, such as purgatives, enemata, massage, etc., might safely be carried out until the supervention of fecal vomiting. 2. That as soon as this was established an exploratory incision into the abdomen should be made without delay. 3. That obscurity of diagnosis, in the presence of this symptom, ought not to be allowed to stand in the way of an operation. 4. That clinical experience showed that there was very little chance of recovery when once stercoraceous vomiting had declared itself unless an operation was performed. 5. That fecal vomiting was a symptom of much more gravity than would attach to the mere mechanical effect of obstruction. 6. That symptoms of collapse were not a contra-indication to operative interference.—*British Medical Journal*, February 23, 1889

Salicylate of Mercury in the Treatment of Syphilis.—DR. SILVA ARANJO, at a recent meeting of the General Polyclinical Society of Rio de Janeiro, read a paper on the therapeutic uses of salicylate of mercury, for which he claimed the following advantages:

1. It is easily supported by the stomach; it does not produce gastralgia, colic, or diarrhœa, symptoms which are so frequently the outcome of the administration of other mercurial preparations, including the proto-iodide and tannate of mercury, which lately have been used very extensively.

2. Salicylate of mercury never produced mercurial stomatitis.

3. Taken internally it acts with greater promptness than any other mercurial preparation heretofore used.

Hearing of Dr. Aranjo's statement, Dr. Carl Szadek, of Kiev, administered this remedy to twenty-five syphilitics, and from the results he obtained confirms the statement of Dr. Aranjo.—*L'Abeille Médicale*, January 31, 1889.

Spontaneous Rupture of the Spleen.—DR. BARRALLIER has recorded two cases of young sailors, about twenty years of age, who both died very suddenly of rupture of the spleen during a first and mild attack of ague. The first returned to his duty, and soon afterward was found dead in his hammock. The peritoneum contained two and a half litres of blood; the spleen was ruptured, and also contained a large clot not communicating with the laceration. The second patient was seized with a sudden feeling of faintness on getting out of bed to go to stool. He was replaced in his bed, but died in a few minutes. The peritoneum was full of fluid blood and clots, and a large rent was found in the capsule of the spleen. In both the above cases the splenic pulp was softened, and there were no adhesions of the capsule to neighboring structures. Dr. Barrallier described in the *Archives Générales de Médecine* a case of an opposite character, very instructive for the sake of comparison. The patient was a workman at the Rochefort Arsenal, aged fifty-four, intemperate, prematurely old, and for long subject to ague. He fell from a height, and struck the left side of the lower part of the thorax against a stove. Symptoms resembling those of hæmato-thorax set in; aspiration was performed, but the patient died a fortnight after the operation. The spleen was enormously enlarged, its capsule thickened and inflamed and universally adherent. There was, in the upper part of the organ, a cavity apparently representing a subcapsular rupture. The spleen projected upward, so that it was capped by the adherent diaphragm, and encroached on the left thoracic region. The enlargement and inflammation of the capsule were, to a certain extent, recent. The peritoneum was free from blood. Thus a severe blow was not sufficient to rupture the thickened capsule of a spleen long enlarged, whilst very gentle exertion caused, in two instances, the rupture of a spleen softened by recent disease, the capsule being thin, and not adherent to the neighboring structures. Hemorrhage in the latter cases soon destroyed life; the former did not die until morbid processes were set up afresh in the injured organ.—*British Medical Journal*, February 16, 1889.

Some of the Abuses of Etherization.—DR. GEORGE F. SHRADY, of New York, concludes an article upon this subject with the following *résumé*:

1. In commencing the administration of ether, the gradual method is to be preferred.

2. Its employment allows the lungs to empty themselves of residual air, prevents coughing and struggling, and places the organs in the best possible condition to receive and rapidly utilize the ether vapor.

3. After the stage of primary anæsthesia is reached, the more pure ether vapor the patient breathes the better.

4. The shorter the time of anæsthesia, and the smaller the amount of ether used, the less likely are the unpleasant sequelæ to occur.

5. The more evenly it is administered, the less shock to the patient.

6. Anæsthesia should be intrusted to experienced administrators only.

7. Many of the fashionable efforts to resuscitate patients are not only useless but harmful.

8. The minimum amount of force should be employed to restrain the muscular movements of the patient.

9. Mixed narcosis is often advisable for prolonged operations.

10. The utility of the galvanic battery, in threatened death, is yet to be proven.

11. The most trustworthy means of resuscitating desperate cases are artificial respiration, hypodermatic stimulation, inhalation of nitrite of amyl, and inversion of the body.—*Medical Record*, February 23, 1889.

Treatment for the Cure of Perineal Urinary Fistula.—DR. W. THOMSON, of Dublin, recommends in a case of long-standing fistula, with considerable riddling of the perineal structures, in the first place thorough slitting and scraping or clipping out of all fistulous tracts; the retention of a catheter through the perineum for several days, so as to prevent the passage of urine along the old paths; and then the opening of the bladder above the pubes by a small incision, so as to divert the urine in that direction. The suprapubic opening should be maintained until there is firm closure of all perineal

fistulæ. There need be no fear of the superior opening into the bladder remaining permanent, once one is in a position to permit urination by the urethra. The tendency of such tracts is to become obliterated when they are kept at rest and are relieved from the passage of urine through them. If, however, the closing should be delayed, the edges could be pared and the lips be brought together with a pin or two and a twisted suture. —*British Med. Journal*, Feb. 9, 1889.

Treatment of Chlorosis.—Dr. Henry Huchard, who has written extensively upon this subject, affirms the statement of Dr. Trousseau that, as a rule, too much iron is given in this affection. The system always contains some iron, no matter how severe the type of chlorosis; this iron is never so deficient as to warrant the administration of such large doses as are generally given. The author frequently prescribes the following:

℞.—Prepared chalk
Powdered roasted coffee } . āā 3 grs.
Powdered rhubarb
Iron filings . . . . ¼ gr.—M.

Make one capsule. To be taken before each meal.

Chlorotics are very fond of vinegar; its use should not be entirely prohibited, as it stimulates the flow of the gastric juice, as shown by Claude-Bernard. It can, however, be replaced by the following:

℞.—Hydrochloric acid . . . gtt. vj.
Lemon syrup . . . . ℥v.
Water . . . . . ℥iv.—M.

One teaspoonful after each meal.

Constipation is to be overcome with small doses of podophyllin or cascara sagrada. If the uterine functions are abnormal, they must receive treatment.

Many chlorotics cannot take iron in any form; it is then that preparations of arsenic and manganese are of service.

℞.—Extract of cinchona } . . āā ℥ijss.
Extract of gentian }
Arsenate of soda . . . gr. 1½
Glycerine . . . . . q. s.—M.

Make 100 pills. Two pills to be taken at the beginning of each repast for six weeks. Should there be anorexia present, fifteen grains of powdered nux vomica can be added to the above.

Or

℞.—Charcoal (poplar) } . . āā 75 grs.
Oxide of manganese }
Powdered calumba } . āā 8 " —M.
Powdered nux vomica }

Make 20 powders. One powder with each meal in the flatulent dyspepsia of chlorosis.

When, however, iron is well supported, the author prescribes the following, which he has used with the greatest success for some years:

℞.—Extract of cinchona }
Extract of gentian } . . āā 75 grs.
Extract of rhubarb }
Tartrate of iron and potassium 75 grs.
Extract of nux vomica . . 8 "
Oil of anise . . . . gtt. v.
Glycerine . . . . q. s.—M.

Make 100 pills. Two pills before each meal two or three times daily.—*Revue gén. de Clin. et de Thérap.*, February 21, 1889.

Infectivity of Phthisical Sweat.—Dr. Eugenio di Mattsi (*Bulletin Médicale*) has made several experiments to determine whether the perspiration of phthisical subjects (in which Severi, in 1884, found the tubercle bacillus) was infectious or not. In the first series of his researches the author obtained the perspiration by simply scraping the skin with a bistoury. The adhering matter was deposited on a watchglass, and then passed rapidly, three times in succession, through the flame of an alcohol lamp, and then colored after the Koch-Ehrlich method.

These researches, made with the perspiration of eight phthisical subjects whose sputum contained the bacillus of Koch, and at different periods of the disease, proved that the perspiration of phthisical subjects (at least in these instances) contained micrococci of variable dimensions, bacilli similar to those of tuberculosis, and fragments of cells, etc. These deposits, when cultivated, gave rise to the development of two colonies of tubercle bacilli. Four rabbits, inoculated with these cultures, succumbed to tuberculosis. Of ten rabbits inoculated directly with the phthisical perspiration, which was introduced into the anterior chamber of the eye, eight developed tuberculosis.

With the second series the author proceeded differently, the perspiration being only removed after the strictest antiseptic precautions had been taken. The skin was first washed with soap and water, then with alcohol of ninety per cent., then with a sublimate solution of 1: 1000, and lastly with sterilized water; the body was then thoroughly dried, and a large watchglass applied, wherein the perspiration accumulated; this glass was removed after two or three days. The experiments made with this perspiration gave results which were absolutely negative so far as the search for tubercle bacilli, the cultivation and the inoculation of animals were concerned.

From these experiments the author reaches the following conclusions:

1. The perspiration of phthisical subjects contains the bacillus of Koch, and is consequently infectious.

2. These bacilli are not eliminated from the body through the perspiration, but come from the sputum of phthisical subjects, and are suspended in the air and attached to the linen of the patient.

3. Phthisical subjects should not spit on the floor, and their wearing apparel should be disinfected before being handled.—*Gazette Médicale de Montréal*, January, 1889.

Ignipuncture of the Tonsils.—Dr. Wilhelm Roth, of Fluntern, finds that in order to reduce the size of the tonsils without risk of troublesome hemorrhage, which is not uncommon, especially in young subjects, the best plan is to employ ignipuncture, as has been recommended by Krishaber, and more recently by Verneuil. The tonsils and neighboring parts are first brushed over with a ten to twenty per cent. solution of cocaine. The finest point of the thermo-cautery, heated to redness, is then inserted to a depth of about five millimetres in three or four spots a few millimetres apart from one another on the tonsils. The instrument is not allowed to remain more than one or two seconds in the tissue. The whole operation, in-

cluding both tonsils, can be performed in a very few minutes without any bleeding, and with scarcely any pain. It must be repeated four or five times at intervals of two or three days, and this is usually sufficient to cause the tonsils to return to their ordinary condition.—*Lancet*, February 16, 1889.

The Prevention of Rabies by Pasteurian Inoculation.—The inoculations performed last year at the Odessa Bacteriological Station against bites from rabid animals show results no less satisfactory than those of the preceding year. The number of persons inoculated was 454; of these, 398 were bitten by rabid dogs, 38 by cats, 7 by wolves, 3 by a man suffering from hydrophobia, 1 by a rabid cow, and another by a wild boar. Six persons underwent inoculation simply as a preventive measure. The patients actually bitten by rabid animals may be divided into three classes. First, are the dangerously wounded—that is, persons bitten on the head, face, or arms; of these there were 89. Of the second class—the slightly wounded—there were 206; and in the third category, of those who had received bites through their clothing, there were 158. In only 44 out of the total 454 cases treated was the actual presence of rabies in the animals inflicting the bites not conclusively proved. Two patients died after the inoculatory course prescribed, but both these cases belonged to the dangerously wounded class, one of these patients being dreadfully lacerated about the head by a rabid wolf. Altogether six patients died during or after the inoculations. Of 7 persons bitten by the same rabid wolf, 1 succumbed. Of 44 persons bitten by other rabid animals, 5 died, giving a percentage of 11; of these, 4 were dangerous cases. In the 158 who were bitten through the clothes there was no fatal case.—*British Med. Journal*, Febuary 16, 1889.

Treatment of Erysipelas.—DR. W. EBSTEIN, of Breslau, details a method introduced by Prof. Rossenbach into the Allerheiligen Hospital of that city. The basis of this treatment consists in limiting the spread of the disease to as small an area as possible. To accomplish this the healthy skin surrounding the infected portion is thoroughly cleansed with soap and water; then a strip of healthy skin, bordering on the diseased portion, is, after being thoroughly dried, anointed with five per cent. carbolated vaseline; this done, the same ointment is applied to the diseased portion, but in order to avoid infecting any healthy tissue, *the applications must be made from the healthy toward the diseased portion and never the reverse.*

The result of this treatment (which was applied to twenty-seven cases of erysipelas of the head, face, neck, and leg) were most satisfactory. All recovered; the duration of the disease was relatively a short one, and in but few instances did the affection overstep the boundary line; and when it did, only for a short distance, and for a brief period.—*Deutsche med. Wochenschrift*, February 7, 1889.

Thymol in the Treatment of Typhoid Fever.—At the Congress of Medicine held in Rome last October, DR. TESTI related his experience of thymol in more than 150 cases of typhoid fever treated in the hospital of Faenza. The results were most satisfactory. The temperature was reduced not, he maintained, by the withdrawal of heat from the body, as is the case with ordinary antipyretics, but by moderating its production. The antiseptic action of the drug was also marked; it diminished tympanites, checked diarrhœa, and notably lessened the putrefactive products usually found in the excreta. Dr. Testi also states that on microscopic examination he found a remarkable diminution in the number of mucous corpuscles, epithelial débris, and parasitic elements (especially granular) in the stools. The drug has also a marked effect in reducing the excretion of urea, and as it increases the blood pressure it has no injurious influence on the action of the heart. Dr. Testi strongly recommends thymol in typhoid fever as mitigating the severity of the disease and preventing complications.—*British Medical Journal*, February 23, 1889.

The Duration of Pregnancy.—DR. CLEMENT GODSON, in a paper in the twenty-fourth volume of the *St. Bartholomew's Hospital Reports*, discusses a recent *cause célèbre* in which the duration of pregnancy was one of the questions in dispute. The mother of the child whose legitimacy was in question, had eloped on June 30, 1884, and a divorce had been obtained in consequence. She was taken in labor at four A.M. on April 2, 1885—*i. e.*, 276 days since she had left her home, and it was not denied that she had slept with her husband up to that time. She had commenced to menstruate on the evening of the day before she left her home, that being the proper date for the appearance of the menses; the menstruation was, however, slight, and ceased on the third day, whereas previously it had always lasted a week. There were, therefore, two points raised against the legitimacy of the child: first, the duration of the pregnancy, 278 days, and second, the menstruation after conception. These points are discussed by Dr. Godson at some length, and he shows conclusively that 278 days is by no means an unusually long period for gestation, and that menstruation during the early part of pregnancy is quite common; indeed, it seems to be the rule almost that conception takes place just before a menstrual period is expected. The jury, however, found a verdict against the legitimacy of the child, after a deliberation of only two minutes, their decision doubtless resting on purely moral considerations, certainly not on any legal presumption, which would have been the other way.—*London Med. Recorder*, Feb. 20, 1889.

Bismuth Salicylate in the Treatment of Diseases of Children.—DR. EHRING has employed bismuth salicylate (Merck's) in 200 cases of dyspepsia, acute and chronic gastric catarrh, gastro-intestinal catarrh, enteritis, phthisical diarrhœa, acid diarrhœa, and dysentery. He gives it, suspended in glycerine or mucilage, because of its insolubility, and because children take pills and powders badly. It is not contra-indicated in constipation. The urine soon becomes more acid, and gives a distinct salicyl reaction; the stools never give this reaction, but quickly become dark in color. He has never seen symptoms of poisoning. He is far from seeing in the remedy a panacea for all cases, but says that when combined with a suitable diet it is most useful and worthy of trial. Its action on the urine suggests that its employment in cystitis may be advantageous.—*London Med. Recorder*, February 20, 1889.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, MARCH 16, 1889.

THE CONNECTION BETWEEN POLLUTED WATER AND TYPHOID FEVER.

THE wide distribution of typhoid fever over the surface of the globe, amongst civilized nations at least, and the great mortality which it causes every year, have imparted to the question of its prevention a very general interest. As prevention depends upon a knowledge of the cause, the discovery of the potential agent and the mode of its propagation and the means of its communication are the prime objects of investigation. The germ theory of the origin of typhoid fever seems to have been established upon a substantial basis. The media by which the infection gains access to the human body are various. The digestive tract is the main avenue of entrance of the microörganism, which is frequently contained in water and food.

From the liability of water to contamination, it has been the principal subject of investigation in all attempts to discover the origin of epidemics of this disease. The well-authenticated outbreaks of typhoid fever dependent upon the use of water polluted by the dejecta of fever patients would seem to leave no room for doubt that water is a common means of conveying the pathogenic organism which incites the disease; and while our knowledge of the subject is not sufficiently precise to warrant exact deductions, there is not wanting evidence of the cumulative sort in connection with recent outbreaks of typhoid fever, which is so conclusive of the mode of infection by specifically contaminated water as to justify its acceptance even without the positive demonstration which improved methods of bacteriological investigation will some day be able to furnish.

At the International Congress for Hygiene and Demography, recently held in Vienna, the relation of the water-supply to the origin of diseases formed a prominent subject of discussion. Numerous instances were related of the influence of drinking-water in spreading infectious diseases, especially typhoid fever. Most of the epidemics described were of recent occurrence, and the evidence seemed to indicate that polluted water was the starting-point of all these outbreaks. The absence of proof of the existence of the specific bacillus in the water before the epidemic occurred, and our inability to differentiate with certainty between the typhoid bacillus and similar bacteria found in water and in the soil, were mentioned by Hueppe and Emmerich as weakening the chain of evidence. The section, however, unanimously adopted the following proposition: "In view of the demonstrated possibility of drinking-water and water used for domestic purposes giving rise to disease, the provision of good, unsuspicious water is one of the weightiest measures of public health."

It would be well if the water purveyors of our cities would adopt this maxim as a guiding principle. Sewage contamination of our rivers, which are the chief source of domestic water-supply, is increasing year by year. The increasing prevalence of typhoid fever would seem to point to this unwise and pernicious practice as the cause. Foreign countries have learned by disastrous experience the unwisdom of this practice. Shall we profit by this experience, and, without waiting for the inevitable, prevent that which it will be infinitely more difficult to remedy in the future?

THE PYLORIC SPHINCTER.

THE cause of the relaxation of the sphincter pylori in order to permit the passage of the chyme is a problem of which the solutions hitherto proposed are unsatisfactory. After reviewing the principal hypotheses advanced to explain this phenomenon, OPPENHEIMER (*Deutsche medicinische Wochenschrift*, No. 7, 1889) concludes that its cause is not to be found within the stomach, but that, on the contrary, every irritation within that viscus causes a contraction of the pyloric orifice. Several facts speak strongly in favor of the view that an irritation in the small intestine is the starting-point of this

passive movement. For example, in cases of ileus, the contents of the intestine enter the stomach and, on the other hand, in cases of intestinal fistula situated near the stomach, it has been observed that the contents of the latter are emptied into the intestine much more rapidly than under normal circumstances. Finally, the administration of cathartics, which exert their irritant action solely upon the intestine, causes a rapid evacuation of the contents of a dilated stomach.

In accordance with this view, the relaxation of the sphincter is the result of certain muscular actions which have their origin in the duodenum. It has been the custom to regard the longitudinal muscular layers of the stomach as starting from the œsophagus or the cardiac orifice, spreading over the borders and surfaces of the organ, passing, some of them, beyond the pylorus and becoming continuous with the longitudinal layer of the duodenum. It is just as easy, as Oppenheimer suggests, to regard the latter fibres as arising in the duodenum, of which the vertical portion affords them a comparatively immovable point of attachment. The contraction of these fibres synchronously with that of the thick longitudinal band occupying the smaller curvature, which is continuous with the fibres of the right side of the œsophagus, will, according to the author quoted, draw the pylorus somewhat obliquely to its usual plane and, at the same time, open its orifice.

The next question concerns the source of the irritation which excites the contraction of these gastro-duodenal fibres, and a clew to its answer is given by certain observations of Oser. This experimenter found that irritation of the splanchnic nerve within the chest causes relaxation of the pyloric orifice. This is readily demonstrated by hydrostatic pressure. A certain amount of such pressure in the duodenum will overcome the pyloric resistance, but a decidedly smaller amount will do so if synchronously with its application the splanchnic nerve within the chest be irritated. Oser supposes the nutriment absorbed by the blood during stomachal digestion to be the physiological irritant which excites this motor action of the splanchnic. This explanation is unsatisfactory, and is not accepted by Oppenheimer, who thinks he finds a better in one of the immediate consequences of Oser's experiment, viz., anæmia of the duodenal bloodvessels. According to this theory, when the duodenum is empty, its bloodvessels are anæmic and the pyloric orifice is open. The chyme now enters it, causes congestion of its bloodvessels and the sphincter closes. The duodenum empties its contents into the ileum, again becomes anæmic, and again the sphincter opens, and so on until the stomach has become empty.

The theory is in harmony with the physiological facts of muscular contraction, but cannot be generally accepted until experimental evidence is brought to its support. Certain apparent contradictions which it involves must also be reconciled. Examples of these are found in the statement that the stomach empties itself with more than normal rapidity after the administration of a cathartic which exerts its action solely on the small intestine, as well as in cases of intestinal fistula seated near the pyloric orifice. Certainly in the former case and, in all probability, in the latter, the condition of the bloodvessels of the duodenum is one of congestion.

It would apparently be a simple matter to repeat the experiment of Oser from the stomach side of the sphincter. If the view of Oppenheimer is correct, the degree of pressure necessary to overcome the pyloric resistance would be materially lessened by exciting the contraction of the gastro-duodenal fibres. Admitting this view to be upheld by experimental facts, it would still remain to be determined whether the contractions of these fibres have their physiological origin in anæmia of the duodenal vessels, a problem which, from the nature of the case, would be much more difficult.

AT the annual commencements recently held, the degree of Doctor of Medicine was conferred on graduates as follows: University of the City of New York, 180; Bellevue Hospital Medical College, New York, 138; University of Tennessee, 61.

THE Johns Hopkins Hospital will be opened to the inspection of the public, before the reception of patients, during the week beginning May 6, 1889.

On Tuesday, May 7th, at 11 o'clock in the morning, there will be appropriate addresses in the main administration building. Invitations to be present will be sent to the authorities of the city and State, to those who have rendered special services in promoting the plans of the Hospital, to professors of medicine and surgery, to the chief managers of other hospitals, and to the representatives of the press.

The Dispensary will be opened for the treatment of outdoor patients on Monday, May 13, at 10 o'clock. The Hospital will be opened soon after-

ward for the treatment of patients sent to it by the head of the Dispensary.

The Kentucky State Medical Society holds its next annual meeting at Richmond, during the second week in May. This promises to be a meeting of special interest, from the fact that the new medical practice act goes into operation on the first of April next, and the profession has not risen to a recognition of the importance of the registration provisions of the act. It is reported at Louisville, for instance, that not one in five of her qualified practitioners has registered, although less than thirty days remain of the time given by law for the registry. It would seem a matter for regret if a want of harmony in regard to some points of minor importance should militate against a cordial support of this progressive measure. All those who are quackishly inclined will inevitably use any alleged indifference and neglect on the part of the better class of physicians as an argument against the adoption of any legislative steps toward the purification of medical practice. The law may not be the most perfect of its kind, but it has been endorsed by the State Medical Society and by the State Board of Health, and is at least an entering wedge for stronger reformatory measures. Let it have a fair trial.

The North Carolina State Sanitary Association held its first annual convention in February, which was largely attended by physicians and sanitary officers. The movement is in harmony with the State Board of Health, and will have for one of its first objective points the promotion of pure water supplies for those towns and cities which have neglected this important requisite.

Dr. S. Weir Mitchell has just been elected a corresponding member of the Verein für innere Medicin, of Berlin.

The students of the Charleston Medical College have presented a memorial cup to Dr. John Guitéras, on the occasion of his leaving Charleston to assume the duties of his professorship at the University of Pennsylvania.

The Russian Government is about to erect a building for the education of women in medicine. The graduates of this institution will be compelled to limit their practice to the treatment of women and children.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, March 7, 1889.

The President, Alfred L. Loomis, M.D., in the Chair.

Dr. Francis Delafield read a paper on

THE TREATMENT OF ACUTE AND SUBACUTE NEPHRITIS.

(See p. 287.)

Dr. Thomas E. Satterthwaite, who was expected to take part in the discussion, was unable to be present, but sent a communication on the subject, which was read by the Secretary.

In considering the treatment of Bright's diseases, whether we call them acute, subacute, or chronic, two important facts, he said, at once confront us. One is, that there are quite different pathological conditions underlying the several manifestations of these affections; the other is, that very few of them are primary diseases, but rather dependent on some antecedent morbid condition or dyscrasia of the general system. He presumed, of course, that we were discussing such kidney troubles as are associated with the classical group of symptoms that relate to serum-albumin, casts in the urine, altered specific gravity, disordered digestion, abnormal volume of water, etc., all of which we find in the following pathological states:

1. Where there is simply renal congestion.
2. Acute diffuse nephritis.
3. Chronic diffuse nephritis.
4. Acute parenchymatous nephritis.
5. Chronic parenchymatous nephritis.
6. The sclerotic kidney.
7. The waxy kidney.
8. The gouty kidney.

He did not wish to appear as pretending that we can always diagnosticate each of these several forms of Bright's disease, or that it is essential for us to do so; but he did desire to have it understood that the more clearly the pathological condition of the kidney and its relation to disease elsewhere in the body is appreciated, the better is the physician prepared to treat it successfully. And his experience had taught him that any intelligent and properly trained physician, after thorough examination into a case of Bright's disease will rarely err in properly classifying. Hence these remarks had a practical bearing on the matter of treatment; for, supposing that our patient had a tumor pressing on the renal veins, or that there was a sudden embarrassment of the pulmonary circulation from a pericardial or pleuritic effusion, and that symptoms of renal inadequacy immediately supervened, it was plain to any one that our efforts should first be directed toward removing the cause. In other words, we should try to get rid of the tumor or dissipate the fluid. Of course, general treatment for the urinary symptoms was important, according to the gravity of the situation. Or, suppose that we have under consideration a case of acute diffuse nephritis from a blow on the loins, or from exposure to cold, or perhaps from an operation along the line of the genito-urinary tract. It is apparent now that the disease is intrenched in the kidney, and is

purely a local affair. Hence, any of the recognized forms of treatment which will restore the normal function of the kidney will apply here.

But in chronic diffuse nephritis, it matters not what is the stage of the disease, whether the organ be pathologically large or medium sized, or small, ultimate success depends largely, he thought, on our ability to manage certain antecedent or concomitant affections; for he believed that articular rheumatism and endocarditis or pericarditis are its determining causes in from fifty to seventy-five per cent. of all cases, and also that phthisis has some etiological relation, the nature of which is very obscure, to the disease. Other factors, too, have their influence, but he considered it comparatively rare for what has been called the acute idiopathic form to become subacute or chronic. Hence it follows that we should always aim to counteract the prevailing diathesis, be it rheumatic, or lithæmic, or phthisical; and it is more especially in this variety of Bright's disease that the diet should be carefully ordered.

Again, in acute parenchymatous nephritis there is an antecedent and determining disease in most cases, probably in all. It is the kidney type of diphtheria, the exanthemata, such as measles or whooping-cough, pneumonia, and the continued fevers. In fact, it seems as if the affection resulted from increased work thrown on the kidneys, owing to the temporary embarrassment or inactivity of other emunctories. Hence, too, no absolute rules can be laid down for treating all these cases. In diphtheria we may press the skin and bowels into service to aid the kidneys; but in the eruptive fevers we have only the lungs and the bowels to work upon. He thought there could be little doubt, however, that the lungs are capable of exhaling a large amount of effete matter.

Now, in chronic parenchymatous nephritis it is also well to remember that the disease is secondary, existing as it does in fully seventy-five per cent. of all cases of pulmonary phthisis, and also that the fatty infiltration, or even degeneration, of the renal parenchyma is not necessarily destruction of the texture of the kidney. In fact, there is reason to believe that, with a cessation of the suppurative process, there is, to some extent, a corresponding diminution in the fatty deposit within the epithelial cells and a more or less perfect return to the normal state. Hence, when this form of lesion exists, the suppurative process must be checked and subdued if we expect any permanent relief for the patient. This statement applies equally well to the treatment of the waxy state; for it is to be presumed that a waxy infiltration of renal vessels is not necessarily permanent. Finally, in the sclerotic or contracted kidney we have a disease that contrasts markedly with the other forms, since, owing to the profound implication of the vessels and heart, accidents are always prone to occur along the line of arterial distribution; so that the danger of hemorrhage is here superadded to those of cardiac or respiratory failure, any one of which may cause instantaneous death, without much previous warning.

Here, then, are some special indications that are to be met, and which can be met successfully, for the time, at least, by remedies that lessen arterial tension, such as ergotin, glonoin, or the bromides. But, after all due recognition of these special considerations which govern each of the different classes of cases, and separate examples of each variety, there are certain general methods that are no less essential to utilize in combating individual symptoms. And, first, we do well to remember that the kidney can be safely stimulated in almost any event. Local applications are usually of the greatest value, especially in urgent cases. To the loins may be applied dry cups (wet cups are seldom needed), rubefacients, and ordinary poultices. The digitalis poultices often used in our hospitals for cases of suppression are effective, but may produce alarming symptoms. In subacute cases, associated with a lithæmic history, salicylic acid in ten grain doses three times a day will not only counteract the lithæmic vice, but promote the flow of urine.

In more or less chronic cases, the muriated tincture of iron will decidedly increase the flow of water, and Dr. Satterthwaite is in the habit of giving it often for months at a time. In less chronic cases, he combines it with Hofmann's ether. The free use of cold water as a beverage, in large quantities, is also of great value, as it scours the kidneys and rids them rapidly not only of excrementitious matter, but also of casts and degenerated epithelium. Alkalies have also a diuretic effect. He usually employs them where the patient has an alcoholic history. They are especially useful in the nephritis of pneumonia, and five grains of the carbonate of ammonium given every three hours to an adult will considerably increase the urine, while it has a most favorable action on the heart. But probably no remedy is so generally useful in urinary insufficiency as digitalis. Drachm doses of the infusion given at intervals of from three to four hours will almost certainly stimulate the kidneys to increased action, especially where the changes are chiefly in the epithelia.

To promote elimination by the bowels (an object to be held in view when treating eruptive diseases), occasional simple saline laxatives usually answer well, as they promote watery evacuations. If more brisk catharsis is needed, Rochelle salts in repeated doses will be effectual. In subacute or chronic cases, where constipation is a troublesome feature, he uses nux vomica, in pill form, for weeks and months at a time; and he has sometimes been surprised at the tolerance shown for the drug when continuously given in large doses. Hydragogue cathartics he seldom uses, except in extreme dropsy, and he then relies on elaterium in quarter of a grain doses.

Elimination by the skin he finds best accomplished by simple diaphoretics, such as spiritus Mindereri, or tincture of aconite root. When either is ineffectual, it may be found that the hot-air bath will prove a satisfactory substitute. Although he does not place much reliance in the hot-air treatment, because it is often disappointing, and thus a source of annoyance to the patient, there are instances where it alone will restore health. In the chronic nephritis of old people it may prove superior to all other remedial agencies. Given before bedtime, if free diaphoresis occur, it commonly induces quiet sleep. Pilocarpin in his hands has been a successful, and, at the same time, a dangerous agent. He has known it to save life and restore to comparative health, when the patient had long been buried in a profound coma; but he has also known the same amount given to the same person under apparently similar circumstances produce the most alarming symptoms. The physician who has decided to administer this drug should give it himself, and be prepared to treat the alarming syncope that may

supervene when its physiological effect has been obtained.

Nausea and vomiting, he believes, are best controlled by mercurials, and he has been in the habit of giving the hydrargynum cum creta, in five grain doses, every three hours. Calomel in small doses, say, of one-tenth of a grain, is also efficient, but there is, of course, the danger of salivation associated with its use. The act of vomiting, however, is sometimes salutary, as the stomach thus gets rid of poisonous excretions; and it is seldom a symptom that requires special treatment.

In conclusion, he stated that the successful management of Bright's disease calls for many kinds of remedial measures, and experience alone in any given case may, after all, have to be relied upon to determine what is the best mode of procedure. In the brief space of time at his disposal he had only had opportunity to outline some of the most manifest considerations in the treatment of this affection, as he reviewed it by the light of his personal experience.

DR. A. JACOBI said that the treatment which Dr. Delafield had so admirably outlined was, for the most part, that adopted by all rational physicians of the present day. His view of the subject of nephritis was much simpler than that indicated by Dr. Satterthwaite, with his elaborate classification, and he would recommend to the careful attention of the academicians not Dr. Delafield's present paper, but also the last fasciculus of his studies, in which he had done so much to rid the subject of Bright's disease of its difficulties and complexity.

There were a few points in regard to which he differed from Dr. Delafield. As to caffeine as a heart-tonic, it was, unqestionably, a powerful heart-tonic; but where there was any cerebral trouble he had found by experience that its action was detrimental instead of beneficial. He referred to the case of a woman recently admitted to his service at Bellevue Hospital, in a condition of profound uræmic coma. After the application of leeches to the septum narium, with the result of abstracting considerable blood, the patient recovered consciousness, and she then improved steadily; but he was confident that if he had resorted to the use of caffeine in this case it would have been followed by positive injury.

As to the bichloride of mercury, he had been in the habit for a number of years of employing it in cases of chronic interstitial inflammation of various organs, and he believed it to be the best "antiplastic" agent that we had, to use a term formerly much in vogue. Used for this purpose it should be given in small doses, and its regular administration persisted in for many months at a time. The only cases of cirrhosis of the liver (non-syphilitic) which he had ever seen getting well, were those in which the bichloride was employed in this way. The only cases of tabes, also, which he had seen getting well, or nearly well, were those in which this agent was used, and he referred particularly to one case of tabes in which the patient's condition was quite as good now as it was twenty-six or twenty-seven years ago, when it first came under observation. He had never seen such good results from any other plan of treatment, and he believed that the bichloride was equally efficient in interstitial disease of the kidneys, more especially when such disease was chronic. He had, in fact, used it with considerable success in a number of cases of chronic interstitial nephritis.

In acute nephritis, he thought we should be a little more successful if we took the trouble to look them up. All physicians were prepared to find the disease in connection with scarlet fever, but there were many other affections in which it was liable to occur as a complication. Thus, it was sometimes met with in connection with measles, and much more frequently with typhoid fever. If, therefore, it was more commonly looked for, many cases that now escape observation would be detected, and, doubtless, a considerable number of cases of chronic nephritis would thus be avoided.

That form of nephritis which occurred after the age of forty or fifty, as the result of vascular degeneration, he believed would be frequently benefited by the addition of the bromides to the other treatment. The bromides might be given to the extent of thirty or forty, or even fifty grains a day, but the latter quantity should not be exceeded. Some individuals were old at the age of forty, and the bromides were extremely beneficial when there was an atheromatous condition of the arteries. As to the use of digitalis in nephritis, he thought that it should unqustionably be avoided in the acute stage, on account of its irritant effect (whether this was produced by digitoxin or not); but even in older cases, where a cardiac stimulant was clearly indicated, he generally selected spartein, which had all the good effects, without the deleterious ones, of digitalis.

DR. F. P. KINNICUTT said it was well to bear in mind, in connection with disturbances of the circulation in nephritis, the fact that sudden death might possibly occur entirely independently of uræmia. Thus Goodhart had met with a case of this kind at Guy's Hospital, where dilatation of the ventricles, without valvular disease, was found as a result of the overwork to which the heart had been subjected.

Increased arterial tension was a condition always to be combated, and in overcoming it, he had found the vaso-motor dilators of more service than any other class of agents. Of these, the nitrites are unquestionably the most valuable; nitroglycerine was the drug most often used, and he was entirely convinced of its marked efficiency. In conditions of heart-failure from overwork a little different treatment was required, and here the combination of cardiac tonics with vaso-motor dilators was of most service; as, for instance, strophanthus or spartein with nitroglycerine. As to digitalis, it was apparently harmful on theoretical grounds, and it was better, he thought, therefore, not to use it. It had a tendency to cause the arteries, as well as the heart-muscles, to contract, and its interference thus with the free flow of blood in the vessels might perhaps explain its injurious effect.

DR. J. WEST ROOSEVELT said that in subacute nephritis the high arterial tension was a source of danger, though the nature of this danger was not properly appreciated. Except to the heart, from overwork, and except in old cases, from the degeneration of the vessels, there was no danger from this high tension itself. The trouble really was a spasmodic condition of the arteries and capillaries. Digitalis was apt to do harm by spurring on too much a heart that was already overworked. The vaso-motor dilators, in which he said he would include chloral hydrate, he thought preferable, although even these were somewhat clumsy in their action.

DR. JOSEPH E. WINTERS said that while change of climate, as recommended by Dr. Delafield, was doubtless of great benefit, there were many cases in which it

was impossible to secure this, and some other plan of treatment had to be adopted. In all cases it was important to observe carefully the amount of albumin in the urine, and in many cases of subacute nephritis he thought it well to treat the patients when they first came under observation as if the nephritis was acute: keeping them confined to bed for a number of weeks, if, in the meanwhile, the nutrition could be maintained. By rest, judicious feeding, and attention to the functions of the skin, the amount of albumin could be materially diminished; and, after all, the quantity of albumin passed was almost without exception the one symptom which indicated whether the condition were improving or not. In order to assist in diminishing it the amount of albuminous food taken should be as small as possible. Thus, eggs should be absolutely prohibited, and no meat allowed, except the white meat of poultry. Milk, fish, and an abundant use of fats, such as fresh butter, cod-liver oil, and cream are relied upon principally for maintaining nutrition. Iron was commonly used in the anæmia of subacute nephritis, but he should like to inquire whether it was well assimilated or not. When there was considerable œdema present he believed that the prognosis was better, so long as the serous sacs were free from it, than when it was very slight. The patient suffered less and was less liable to convulsions and other serious uræmic disturbances; and this might, perhaps, be because some of the urea found its way into the serum beneath the skin.

DR. LAURENCE JOHNSON said that he should like to say a few words in regard to the use of pilocarpin, alluded to by Dr. Satterthwaite. In acute uræmia he had been accustomed for a number of years to employ this agent with the happiest results, and especially in this condition when connected with pregnancy. Within the last few days he had been called to see a lady eight months pregnant, who was suddenly seized with a convulsion, without having previously had, so far as known, any kidney disease. Before he saw her she had had five convulsions within six hours, and the urine was found, on examination, to be heavily loaded with albumin. He immediately gave one-sixth of a grain of hydrochlorate of pilocarpin; in fifteen minutes a second dose of the same size, in twenty minutes more a third dose, and in two and a half hours later a fourth dose. The transudation of liquid produced by the drug was enormous, but there was no weakening of the heart. Within six hours the secretion of urine was reëstablished, and the subsequent improvement of the patient was entirely satisfactory. In one similar case that he recalled there was complete loss of vision. The patient was eight months pregnant, and delivery was promptly and forcibly accomplished. Vision was completely restored, and the child, as well as the mother, was sound. In still another case in which the pilocarpin was used with the happiest effects, the patient had convulsions before, with, and after delivery. Some time since he saw in consultation with Dr. J. Lewis Smith a child nine years of age, who was suffering from acute uræmic poisoning as a complication of simple bronchitis, and here, also, the pilocarpin was successfully employed.

In these acute cases of uræmia he would hardly know how to get along without this valuable agent. To help the patient over the immediate danger of such attacks he was not acquainted with any agent so efficient. Of course, it should be employed only in properly selected cases, and in very weak subjects he could readily see how it might do harm. When the patient was fairly well nourished, however, it was invaluable in the uræmia of acute nephritis and the exacerbations of subacute nephritis, and he had never seen any ill effects result from it.

DR. A. L. LOOMIS believed that it was Dr. Delafield's intention to exclude the consideration of chronic Bright's disease from the present discussion, limiting it entirely to acute and subacute nephritis. When a physician was called to a case of acute or subacute nephritis, it was of the greatest importance that he should inquire—*first*, what the condition of the patient was at the time the attack came on; *second*, his age; *third*, his predispositions; and, *fourth*, his habits. The treatment that would be judicious and acceptable in a child, would not be judicious and acceptable in a man of fifty; just as in pneumonia, the difference in the probabilities and management of a case at twelve and a case at fifty would be very great In cases of acute nephritis rest in bed, a liquid diet, and mild purgatives were all he had required, unless there were noted disturbances indicating the retention of excrementitious products in the blood from which convulsions or other serious troubles might result. In most cases, and especially in young subjects, there was high arterial tension, and we should endeavor to relieve this tension by means of calomel and salines. If there was a drug which would relieve high arterial tension, it was calomel, in small doses and frequently repeated; and this was admirably supplemented by the free use of salines. The internal use of these agents, with the application of dry cups and stimulants to the surface, was all that was required; and vaso-motor dilators and internal stimulants were, in general, contra-indicated. In the treatment of any case the general condition and habits of the patient were, of course, to be taken into consideration, and the presence of alcoholism or other source of weakness might render certain modifications necessary.

In subacute cases the circumstances are somewhat different. Here he was entirely opposed to all forms of depletion, and consequently he did not believe that the patient should be depleted by hot-air baths or by any of those drugs which had so long been retained by the profession for this purpose. It seemed to him that dependence was to be placed rather upon hygiene and all such measures as would improve the nutrition of the patient. Iron he did not think would do this, but a change of climate was often very beneficial. As to the use of digitalis or other cardiac tonics, he thought one should be guided by a very simple rule. Whenever in subacute nephritis heart trouble is met with, we have a right to resort to some form of heart tonic; but so long as arterial tension remains such agents will only do harm. If, in any case, there was dilatation with heart-failure, and a diminution in the quantity of urine passed, ought we to use digitalis? If by the use of this drug the amount of urine was appreciably increased, he believed that we ought, and he considered that as long as it had this effect it was perfectly safe to employ it. If, however, high arterial tension was present, digitalis would always diminish the urine, and it was, therefore, clearly contra-indicated in any such case.

One point more. He did not believe that there was

any drug which would hold a heart that was weakening from the effects of poisons, such as alcoholism, uræmia, etc., in the system like opium, given in small doses and persistently used. This contributed very materially to the patient's comfort, and was also often instrumental, he believed, in prolonging life. It was to be given for its effect on the circulation.

DR. DELAFIELD, in closing the discussion, said that he had always found one difficulty about the subject in question. Whenever we commenced to talk about acute and subacute nephritis, some one was sure to get off on to chronic Bright's disease. He had not touched upon this at all in the paper, and yet Dr. Satterthwaite's remarks had been principally devoted to it. As to the use of caffeine, referred to by Dr. Jacobi, he had not recommended it himself, but had simply quoted Labadie in the *Nouveau Dictionnaire de Médecine et de Chirurgie*, as advising its administration, in connection with inhalations of oxygen gas, in uræmic coma. Bichloride of mercury was one of the old standbys in subacute nephritis, but he by no means felt satisfied as to whether it was really of service or not. In common with others, he frequently resorted to it himself; but it was never employed alone, and hence it was difficult to say just what its action was. He thought Dr. Jacobi had made a very good point in calling attention to the comparative frequency of acute and subacute nephritis. It was not by any means almost exclusively confined to scarlatina, as many practitioners seemed to think, but was met with in connection with many of the other acute fevers, and not infrequently occurred as an idiopathic affection also. Many young laborers went about their work while affected with acute or subacute nephritis, not considering themselves sufficiently ill to take to their beds; and thus very serious injury was liable to result.

As regards the matter of arterial tension, he thought it was necessary to draw a sharp line between cases of acute and subacute nephritis. When the affection was acute there could be no question that the quickest way to reduce the tension was by the use of small doses of calomel or sulphate of magnesia, frequently repeated. This relief he believed to be due to the effect of the drug on the nephritis itself. Otherwise, it was not easy to see how such agents acted, since, in order to secure the best results, their use should be suspended as soon as a distinct purgative action was produced. In order to relieve the arterial tension, the calomel, or sulphate of magnesia, should be given every hour, just as in peritonitis. This effect having been obtained, it could be held better by aconite, in minute doses, than any other agent with which he was acquainted.

The moment that we had to deal with subacute nephritis, the conditions were found to be altogether different, and no good results are to be any longer anticipated from the use of the agents mentioned. Here we employed the class of drugs that dilate the vessels, and nitroglycerine and chloral hydrate were both efficient in this connection. The use of digitalis did not apply to acute nephritis at all, and in subacute nephritis the indications for its employment had been very clearly pointed out by Dr. Loomis.

In regard to Dr. Winters' remarks, there were two points upon which he felt compelled to take issue with him. The first was, that the quantity of albumin in the urine is the measure of the nephritis present and the general condition of the patient. The amount of urine was only one of many indications to be taken into consideration, and he doubted if it were wise to make this a kind of bugbear. The circumstances were comparable to those in pleurisy, where the amount of the effusion was not to be regarded so much as the violence of the febrile action and the general condition of the patient. The second point upon which he differed from Dr. Winters, was as to the feeding of the patient. He thought it wise to give food without any reference whatever to the amount of albumin in the urine. The kind of feeding should be governed simply by the acuteness of the attack, and when the acute stage was passed, he believed that solids should be freely allowed, except at such times when acute exacerbations occurred. As to the use of iron, he thought that in subacute cases we could sometimes accomplish much with it; and even in cases where it was apparently without effect, we often did not realize how much good it really did, because we did not examine the blood.

A NEW BUILDING FOR THE ACADEMY.

THE PRESIDENT announced that the Academy had secured the refusal of three lots on Forty-third Street, west of Fifth Avenue, for building purposes, the price of which was $90,000, and that a further subscription of from $20,000 to $25,000 was necessary, in order that the project for the new building should be carried out.

MONTREAL MEDICO-CHIRURGICAL SOCIETY.

Stated Meeting, February 22, 1889.

THE PRESIDENT, WILLIAM GARDNER, M.D., IN THE CHAIR.

DR. SHEPHERD exhibited the following specimens of anomalous arteries:

(1) ABNORMAL LINGUAL ARTERY.

This specimen was obtained from a male subject used in the operative surgery class. The artery of the left side was cut down upon in the usual way, but it could not be found; on further dissection of the neck it was seen to come off in common with the superior thyroid opposite the upper border of the thyroid cartilage, from here it passed upward and inward upon the sterno-hyoid muscle to the hyoid bone; it crossed the hyoid bone internal to the lesser cornu, and then pierced the hyoglossus muscle; the rest of its course was normal. Dr. Shepherd stated that the relation of the lingual artery to the great cornu of the hyoid bone was very constant, even if its origin from the carotid was above or below that point; hence the great cornu is usually the guide to the finding of the artery. In this case no part of the great cornu was in relation with the artery. The anomaly, no doubt, originated from the enlargement of the hyoid branches of the superior thyroid and lingual arteries, and a consequent disappearance of the main trunk; a familiar example of this enlargement of anastomotic branches is seen when the obturator comes off from the epigastric artery.

(2) ABNORMAL INFERIOR THYROID ARTERIES,

both coming off from the right side.

Dr. Shepherd said that this specimen showed a rare and hitherto undescribed anamoly. Neither of the in-

ferior thyroid arteries arose from the subclavian. The *right* took its origin from the common carotid artery about an inch from its commencement. The left came off from the innominate artery, crossed over the trachea, and supplied the left lobe of the thyroid. On its coming across the trachea it gave off a small middle thyroid artery.

(3) THYROIDEA IMA AND DOUBLE SUPERIOR THYROID ARTERY.

The thyroidea ima in this case was of large size and divided into four large trunks which completely covered the front of the trachea; it arose from the innominate. Two superior thyroids existed on the left side, the upper of which was of small size.

OÖPHORECTOMY.

DR. ARMSTRONG presented the ovaries and tubes removed from a patient aged twenty-three years. The patient had suffered from the usual symptoms observed in such cases. On opening the abdomen the left ovary was found fixed and displaced, the tubes adherent, dilated, and filled with cheesy matter. There was no tuberculous history; patient had had one child.

DR. ALLOWAY said that the condition resembled that described by Mundé, as pachy-salpingitis. The affection, no doubt, commenced as a pyosalpingitis, and the cheesy matter was inspissated pus.

DR. GARDNER believed that many of these cases were due to prolonged treatment by pessaries for the correction of some displacement of the uterus.

DR. ARMSTRONG stated that this patient had been treated by pessaries for some uterine displacement before coming to him; he said that women with diseased ovaries and tubes were never safe until they were removed, and related a case of ruptured Fallopian tube leading to a purulent peritonitis. The abdomen was opened and drained, but the patient died. The rupture occurred whilst the patient was convalescing from her second confinement.

DR. BELL presented a

TUMOR CONNECTED WITH THE THYROID

which he had removed from a young man, aged twenty-five. When he entered the hospital both lateral lobes of the thyroid were much enlarged, and over the crico-thyroid space, cricoid cartilage, and upper rings of the trachea was a tumor the size of a small orange. The patient was a farmer, and was incapable of pursuing his occupation owing to the severe dyspnœa occasioned by the least exertion. After remaining in bed in hospital for some weeks, there was a marked diminution, not only in the size of the tumor, but of the whole thyroid, and his breathing became much less obstructed. The tumor was easily removed and shelled out from its bed without trouble; it apparently was unconnected with the thyroid, though on microscopic examination it gave distinct evidence of thyroid structure.

DR. BELL also presented large masses of thickened synovial membrane and thickened fringes, removed from a case of

HYDROPS ARTICULI

affecting the knee. The patient gave a history of repeated attacks of gonorrhœa. The knee was first affected six years ago, and had been getting gradually worse till from its size and the great pain on movement it prevented his working. He had suffered at times from inflammation of other joints, such as the ankles, etc. Patient had a well-marked tuberculous family history. An incision was made in each side of the patella, and a large amount of fluid evacuated. The thickened synovial membrane and the large masses of fringes looking like bunches of grapes, were dissected away. The patient was doing well. Dr. Lafleur, who examined the removed tissue, stated that it gave distinct evidence of tubercle. There were abundant granulation-cells with giant cells.

DR. SHEPHERD said that, notwithstanding the results of the microscopic examination, he doubted the tuberculous origin of the affection, and looked upon it as a simple case of hydrops with enormously thickened synovial membrane. The patient had suffered from this affection for six years, and yet the cartilage and bone were not invaded. In his experience he had never seen a tuberculous joint act in this way.

DR. RODDICK agreed with the last speaker, and was not inclined to regard this as a case of tuberculous disease of the knee-joint. The patient had suffered from repeated attacks of gonorrhœa, and at times other joints were also affected. It appeared to him that the case was one of hydrops. The length of time the affection had lasted without invading other structures was against the disease being of tubercular origin.

DR. BELL, in reply, said that he regarded the case as one of tuberculosis invading an already injured joint; he did not believe it was tuberculous in the first instance.

DR. BELL also presented a case of

DRY GANGRENE OF HAND

in which he had performed amputation of the arm. The patient some months ago had an inflammatory attack of the hand which resulted in contraction of the thumb, fore and middle fingers of the right hand. In a few weeks these fingers became dark in color and shrivelled up. When seen by Dr. Bell he had well-marked dry gangrene of the thumb, index, and middle finger—in examining the brachial, no pulsation could be felt below the elbow. Amputation of the arm was performed and an examination of the removed limb showed that the gangrene was due to a thrombosis of the brachial artery at its lower part. The cause of the thrombosis could not be made out; there was no marked atheroma of the vessels; the man had received an injury of the arm whilst intoxicated which might account for the thrombosis.

DR. GEORGE ROSS read a paper on

GASTRIC AND DUODENAL ULCER.

The first case related was one of ulcer of the stomach of long standing. The patient—a woman of fifty-two years of age—had suffered for about ten years from pain after food, sometimes of a very severe character, and frequent vomitings; had been rather pale and not strong for a few years, but had still been able, with effort, to accomplish the work of her household. Her strength finally gave out and she kept her bed. Some months ago she noticed a lump in the epigastrium and observed frequently snake-like movements in that part of her belly; so distinct were these that she became firmly convinced that a live lizard was in her stomach. The tumor was found to be firm, nodulated, movable, hardly tender, and influenced very much by the vermicular movements, which occurred

at irregular, but short, intervals. At the time of the contraction, the stomach was very distinctly felt, rising hard and rounded beneath the band and obscuring the tumor; after a few seconds, it quietly became more flaccid and the tumor more perceptible. The contractions caused pain. The stomach was not at all dilated—in fact, rather the contrary. At the patient's urgent solicitation, laparotomy was performed by Dr. Bell though it was much doubted if anything effectual could be accomplished.

The stomach was found of small size and a firm mass occupied the greater part of the lesser curvature of the organ, encroaching in the posterior wall. It was decided that it could not be removed. She was none the worse for the operation and much relieved mentally; three months later she was still living but in a very weak state. It was stated that some of the consultants considered the case one of malignant disease engrafted upon an old ulcer.

Dr. Ross did not hold this view. He thought the tumor a non-malignant fibroid thickening around the base of a large, very chronic ulcer, and considered that the details of the case bore out this opinion. He said he had often seen tumor of the stomach of this kind reach a considerable size, most frequently near the pylorus. He admitted the fact that malignant disease did sometimes develop in cicatricial tissue, but as to gastric ulcer, though the process is spoken of in this connection, yet it would seem that the facts upon which this statement is based are rather meagre. Extreme rapidity of development and coincident marked emaciation and cachexia must be demonstrated to make clear the existence of malignant disease. The diagnosis might have an important hearing upon the question of operation. The course of the marked peristaltic movements seemed obscure. Dr. Ross had often seen these in connection with pyloric obstruction, but here there was no mechanical narrowing of the outlet.

A second case was reported as a contrast to the former, in which the rapid development of painful gastric symptoms with equally rapid failure of flesh and strength in an elderly man, led to a diagnosis of cancer. A small, tender lump lay immediately under the ensiform cartilage and projected downward with the contractions of the diaphragm. This was believed to be in the liver. The autopsy revealed a contracted stomach with thick walls infiltrated with the malignant growth. No tumor. The lump referred to was a secondary nodule in the left lobe of the liver.

The third case was believed to be one of duodenal ulcer. The patient was a large-framed, young farmer, aged twenty-three. Had suffered from dyspepsia and pain on the left side for six years; soon after had an attack of melæna, passing large quantities of blood, fainted twice, and stayed in bed two months. Dyspeptic symptoms had persisted ever since, with weakness. In November last had a repetition of the intestinal bleeding, and when seen here soon afterward was blanched and feeble. It was thought that all other possible causes of hemorrhage could be excluded, and the diagnosis was discussed with the result that the existence of a duodenal ulcer seemed certain. The situation of the pain was remarkable, being under the *left* hypochondriac region. Examination of the stomach proved it to be in a state of moderate dilatation, succussion sounds being very loud. He vomited occasionally, and sarcinæ ventriculi were present. The explanation of this was, that a partial stenosis of the duodenum existed and acted in the same way as a narrowing of the pyloric opening. The condition is mentioned as one of the rare sequels of duodenal ulceration.

CORRESPONDENCE.

HYPERTROPHY OF THE LINGUAL TONSIL.

To the Editor of THE MEDICAL NEWS,

SIR: The following case of hypertrophy of the lingual tonsil may be of interest on account of its unusual size. Mrs. F., æt. about forty, applied to me for relief from an unpleasant sensation of some obstruction or feeling of stiffness in her throat. She complained of no pain at all but said she had been treated for several months, two or three years ago, for the same sensations, by means of sprays, etc., without deriving any decided benefit. On examination with the laryngoscopic mirror I found two masses of cellular tissue situated just over the line of the papillæ circumvallatæ and extending from the base of the tongue behind the epiglottis almost to the top of the arch of the tongue. Each tumor appeared to be about the size of the first phalanx of the index finger and between them there was a deep channel. There was very little appearance of inflammation or varicosity. I removed one tumor entire with Mackenzie's tonsillotome, and a portion of the other. The patient has since expressed herself as being much more comfortable.

Very truly yours,

W. PEYRE PORCHER, M.D.

4 GEORGE ST., CHARLESTON, S.C.,
Feb. 25, 1889.

CASE OF SUPERNUMERARY DIGITS.

To the Editor of THE MEDICAL NEWS,

SIR: The following case is reported in the hope that it may give some assistance in clearing up the question raised by Dr. T. Wesley Mills, in *The Canada Medical and Surgical Journal* for May, 1887. Prof. Mills there states that, according to Prof. Brooks, variations originate with the male, but himself gives a case which is, at least, an exception to the rule, and, as he says, is much against the theory. It is true that this is a single case, and that the history further back than the grandparents cannot be obtained, but it is given for what it is worth.

On the 15th of February, 1889, I was requested by a man to go to see his baby, a girl, aged two weeks. He stated that when the child was born it had a little tag of flesh on each hand. The mother had been advised to remove them by tying a silk thread tightly around each one. This was done, with the result that one hand was becoming very sore, and the child appeared quite ill.

When I saw the child I found that from the outer side of each little finger, opposite the articulation of the first and second phalanges, there grew a supplementary finger. That on the right hand was still tightly bound by the ligature, and was much discolored; the little finger of that hand was also somewhat inflamed. On the left hand the silk had become loosened and the appendage presented a natural appearance. It increased three-eighths of an inch in length by a quarter of an inch in breadth, and at the distal extremity was furnished with a diminutive nail. It was attached to the left little finger by a pedicle about a quarter of an inch in length, and

was freely movable. Both appendages were removed without any trouble.

In this case there is no history of maternal impression, and the parents are positive that, as far as they themselves and their parents are concerned, there has been no other case of supernumerary digits in either family. Further than their own parents they cannot go. This would, therefore, appear to be a case in which the variation originated with the female.

W. A. DE WOLF SMITH.
NEW WESTMINSTER, BRITISH COLUMBIA.

NEWS ITEMS.

Colds and Clothing.—The teaching of modern science and of ancient custom goes to show that heat-production within the body has much to do with the tissue-changes concerned in muscular activity and with healthy digestion. It is conserved by warm and moderate, wasted in evaporation by excessive, clothing. Finally, by a simple nervous reaction, it is increased after the contact of external cold. It follows from these observations that, if we be so clad with comfortable underclothing that surface perspiration is not formed in excess and is rapidly removed, one great cause of chill—sudden evaporation—is done away with.

Outer cold, then, provided it is not too severe, only touches, as it were, the spring of the heat-making metabolism, and, exciting an elastic rebound in the chain of vasomotor fibres, awakens that oxidative action by which every tissue is made to yield its share of heat to the body. This bracing influence is lost wholly or partly to those who are too heavily clothed, and in its place we may have a dangerous excess of surface-heat. It is for this reason that we have before protested, as we now do, against the indiscriminate use of the thick and heavy overcoat. We would rather see men in fairly robust condition, especially if young, clad warmly next the skin, and wearing either a light top-coat or none at all.

There can be no doubt that the habitual use of great coats is indirectly accountable for the chills which they are intended to prevent. Were the overcoat worn continuously, it might attain its object. Its intermittent use, even when ample underclothing is worn, affords no solid guarantee of safety, but rather the reverse. The man of sedentary habits has especial need to remember this. He emerges daily from a warm breakfast-room clothed in his ordinary winter garments, with probably woollen underwear, and over all the heavy ulster or topcoat. After a short walk he finds that the sense of warmth he began with is more than maintained. He arrives at his office or place of business, and off goes the overcoat, though the air of the newly opened room is as cold as that without, and draughty in addition. During the day perhaps he travels to and from adjacent business houses wearing only his house clothing. The overcoat is laid aside till closing time reminds him of the journey home. The frequent result is that somehow between the hours of his departure and return he is chilled. No doubt he would run as great a risk, if lightly clad, he were to face the rigor of a winter day. In this case, however, exercise and habit might do much to develop the power of endurance, and there would, at all events, be less danger of sudden cold acting upon a freely perspiring surface.

Woollen underclothing represents a state of healthy comfort intermediate between these extremes, and more resistant to chill than either. In commending its use, however, we do not assert that the influence of age and constitution is to be overlooked. Youth can oppose a power of resistance to depressing agencies which does not reside in the worn-out nerve centres of a riper age. Similarly, that elastic reaction which characterizes the nervous and sanguine types is not to be looked for in the lax tissues of the lymphatic. The weaker physique naturally calls for fuller protection than the stronger; and any rule requiring the disuse of the overcoat should allow of reasonable exceptions in favor of the old and constitutionally feeble.

Unusual severity of weather, especially if associated with night air and the loss of sleep which this implies, is another condition which might well constitute an exception. In such a case we are compelled to add some form of overcoat to the ordinary amount of clothing. Some parts of the body—for example, the chest, throat, and feet—are certainly more susceptible to cold than others. As a useful safeguard, cold or tepid bathing of such parts is in merited favor. The custom so common with many persons, especially women, of walking out in thin-soled boots often plays an important part in catching cold. The progress of time and of rational thought may be expected to bring in a more comfortable arrangement by clothing the foot in woollen hosiery and a stouter boot.—*Lancet*, Jan. 26, 1886.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM MARCH 5 TO MARCH 11, 1889.

WEBSTER, WARREN, *Major and Surgeon* (U. S. Army).—Retired from active service, February 28, 1889.—Par. 9, *S. O. 50, A. G. O.*, March 1, 1889.

GREENLEAF, CHARLES R., *Major and Surgeon* (U. S. Army).—Is appointed a member of the Board to meet in this city on March 11, 1889, for the purpose of revising the blank forms now in use in the Army, and preparing the "Book of Forms" for issue.—Par. 13, *S. O. 55, A. G. O., Washington, D. C.*, March 8, 1889.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING MARCH 9, 1889.

MARSTELLER, E. H., *Passed Assistant Surgeon.*—Detached from the monitors at Richmond, and wait orders.

CABELL, A. G., *Passed Assistant Surgeon.*—Detached from the Naval Hospital, Chelsea, Massachusetts, and ordered to the monitors at Richmond.

MCCLURG, WALTER A., *Passed Assistant Surgeon.*—Promoted to the rank of surgeon.

BABIN, H. J., *Surgeon.*—Detached from the "Mohican," proceed home, and wait orders.

BRADLEY, GEORGE P., *Surgeon.*—Ordered to the "Mohican."

LUNG, GEORGE A., *Assistant Surgeon.*—Detached from the "Vermont," and ordered to the "Mohican."

ORIGINAL LECTURES.

ACUTE PANCREATITIS.

A Consideration of Pancreatic Hemorrhage, Hemorrhagic, Suppurative, and Gangrenous Pancreatitis, and of Disseminated Fat-necrosis.

The Middleton-Goldsmith Lecture for 1889, delivered before the New York Pathological Society, Feb. 16, 1889.

BY REGINALD H FITZ, M.D.,

SHATTUCK PROFESSOR OF PATHOLOGICAL ANATOMY IN HARVARD UNIVERSITY AND PHYSICIAN TO THE MASSACHUSETTS GENERAL HOSPITAL.

(Concluded from page 286.)

DISSEMINATED FAT-NECROSIS.

CONSIDERABLE prominence has necessarily been given to the necrosis of fat-tissue associated with pancreatic inflammations.

Hooper[1] probably intended to describe the appearances due to this condition; but Ponfick[2] first distinctly recognized the condition. He called attention to a disseminated necrosis of bone-marrow in a case of empyema and extensive amyloid degeneration. The appearance was that of innumerable, submiliary, yellowish-white specks in the amber-colored marrow. They proved to be composed of an agglomeration of large cells crowded with fine granules. These were enormous, granular corpuscles, which from their size and shape were regarded as identical with fat-cells. There were also narrow and elongated, fatty-degenerated cells, so disintegrated in many places as to form a finely granular detritus. Ponfick attributed these spots of necrosis to a fatty degeneration of the marrow.

Balser,[3] who became an assistant of Ponfick, then professor at Göttingen, found similar appearances in the marrow and in the subpericardial fat, each in an old man. In the examination of twenty-five unselected cases he found such patches in the region of the pancreas in five instances. Two of these patients died of cancer of the stomach, and the remaining three were cases of pulmonary consumption, hepatic cirrhosis, and aortic endocarditis respectively. There remain two additional cases in which he found fat-necrosis.[4]

These he regarded as illustrative of the fatal effect of a disease, fat-necrosis, which, when extensive, was associated with old and fresh hemorrhage. Such hemorrhages near the pancreas might produce death in a manner resembling that described by Zenker as pancreatic apoplexy.

He regarded the fat-necrosis as the result of an excessive growth of fat-tissue which destroyed the tissue it surrounded. From its association it was a special source of danger to fat persons. His conclusion is:[5] "an excessive growth of the fat cells near the pancreas occurs in many men. It may become so excessive, in very fat people, that a large part of the abdominal fat dies, and it thus proves fatal, either on account of the quantity destroyed or the associated hemorrhage.

Chiari[1] had also found fat-necrosis associated with pancreatic disease,[2] although in his published report he made no note of the characteristic appearances. He confirmed Balser's statements concerning the occurrence of fat-necrosis in and near the pancreas. Since he had observed it in five out of six cases of pancreatic disease, a certain connection between the two was suggested. Three of these were cases of sequestration of the pancreas. The remaining three were a phthisical diabetic, a case of chronic Bright's disease and interstitial pneumonia, and an infant with congenital syphilis.

He found no evidence of an excessive circumscribed growth of fat-tissue, as claimed by Balser, but regarded the necrosis as a degenerative process analogous to the retrograde metamorphosis in other tissues, and the result of a severe marasmus. He admitted it as a cause of pancreatic hemorrhage and that it might, hence, prove fatal. He did not regard the sequestration of the pancreas as the result of this necrosis, since he could not understand how extensive circumscribed necrosis about the pancreas could isolate so large an organ.

Finally, Van Giesen[3] presented to the New York Pathological Society microscopical sections illustrative of fat-necrosis. They came from the pancreas of a woman eighty years of age. There were two nodules, the larger five mm. in diameter. Nothing is stated with reference to any associated lesions, and the necroses were regarded as degenerative.

There is a general agreement as to the appearance of these nodules. They are multiple, disseminated, are found in the subperitoneal fat-tissue of the abdominal wall, mesentery, omentum, and in that within and around the pancreas. Chiari[4] found them also in the subpericardial, subpleural, and subcutaneous fat. Their presence in marrow has already been mentioned.

Such nodules were present in one case of pancreatic hemorrhage, certainly in one, probably in two, cases of acute suppurative pancreatitis. They were seen in six cases of hemorrhagic and in six of gangrenous pancreatitis.

These nodules, in most of the cases, occurred in great numbers, the smallest not larger than a pin-head, and strongly suggestive of miliary tubercles or malignant new formations. The largest were of the size of a hen's egg All were more or less rounded, of an opaque white or yellowish-white color, and of soft, tallowy consistency. They occurred alone or in groups, superficially and deep seated. The smallest were often surrounded by an injected vascular wreath, while many were bounded by

a distinct, narrow, reddish-brown zone, indicative of hemorrhage.

Chiari[1] found the larger nodules (although he does not state in which of his six cases) incrusted with lime, and surrounded by a distinct fibrous capsule, from which threads occasionally ran into the surrounding fat-tissue.

The tallowy material could be readily picked out of these nodules, and, when examined microscopically, consisted largely of acicular crystals resembling those found in fat, in addition to fat-drops and a granular detritus. Dr. Harrington's micro-chemical examination of these crystals shows their identity with those obtained from tallow. He regards them as stearine. In this view he confirms the conclusion reached by Balser.[2]

The microscopical appearances have already been described in sufficient detail.

Balser states[3] that his examination shows that the same process is concerned in the mild and fatal cases. Neither he nor Chiari was able to find any evidence of a bacterial or mycotic process, nor was the latter able to discover any changes in the neighboring vessels.

The microscopical appearances found in Case LXVII. make evident certain features in the more serious fat-necrosis, which supplement the results described by other observers.

Tracts of round-celled infiltration were found at the border of the patches. Chiari also states that the fibrous threads continued from the capsules were infiltrated with round-cells.

The surrounding fat-tissue gave frequent evidence of an acute lymphangitis, of abscesses, and of thrombosis.

Bacteria were found in and near the patches of necrosis. They were likewise present in a neighboring vessel and in a venous thrombus.

The association of these appearances with the evidences of fat-necrosis indicate most directly that the latter condition, in fatal cases at least, instead of being simply the result of a hyperplasia or of a degeneration, is connected with an acute, inflammatory process, somewhat akin to the phlegmonous inflammation of the subcutaneous fat.

The cause of its dissemination would thus, probably, depend upon the transfer of an infecting material, either through vascular currents, especially lymphatics, or by direct inoculation of the peritoneum in case of the superficial nodules. The multiple, disseminated fat-necrosis found associated with fatal pancreatic disease is thus to be regarded as the result of the inflammation of the fat-tissue extended from the pancreas or its vicinity. The pancreas is usually the seat of the primary process, but the necrotic inflammation of the fat-tissue may be secondary to a possible primary lesion of the biliary tract or stomach, as suggested by Cases LVII. and LVIII.

The spots of dead fat-tissue, observed in the marantic cases may be degenerative, as claimed by Ponfick and Chiari. They certainly are neither necessarily nor exclusively found in fat persons. There is no confirmatory evidence of their hyperplastic nature.

The inflammatory fat-necroses, in most cases, were associated with evidences of putrefactive conditions.

It would thus appear that there is a necrobiotic necrosis of the fat-tissue, and an inflammatory necrosis, the latter tending to become gangrenous, both of which may be found within or near the pancreas. The inflammatory and gangrenous varieties are of especial importance in permitting the sloughing of the pancreas, and in most instances are the result of an acute inflammation of this gland.

Although the serious varieties of fat-necrosis may be recognized as causes for sequestration of the pancreas, their relation to pancreatic hemorrhage must be expressed in different terms from those employed by Balser and Chiari.

A simple, necrobiotic fat-necrosis may be associated with fatal pancreatic hemorrhage, as suggested by Case V., but there is no necessary etiological significance in this association. Most fatal cases of pancreatic hemorrhage occur without either variety, and the simple necrosis usually takes place without hemorrhage.

When the severe varieties of fat-necrosis accompany pancreatic hemorrhage, inflammation of the pancreas is present. The fat-necrosis cannot be regarded as the essential cause of the hemorrhage in such cases, since it occurs in suppurative pancreatitis when there is no hemorrhage in the pancreas.

Furthermore, when hemorrhages are found near the necrotic patches they are usually very slight and limited to the immediate vicinity of the patch.

CONCLUSIONS.

The evidence presented in this paper is intended to establish the fact that—

Acute inflammation of the pancreas is both a well-characterized disease, and one which is much more frequent than is generally thought.

It is of great consequence that it should be recognized, for the following reasons:

It represents a serious complication of what, by itself, is a relatively simple affection, viz., gastro-duodenitis.

It is an important cause of peritonitis, and one readily overlooked.

It has been repeatedly confounded with acute intestinal obstruction, and has thus led, in several instances, to an ineffective laparotomy; an operation which, in the early stage of this disease, is extremely hazardous.

METHOD OF ORIGIN.

Acute pancreatitis commonly originates by the extension of a gastro-duodenal inflammation along the pancreatic duct. It may also be induced by the occurrence of hemorrhage in the pancreas. This may be of traumatic origin, although usually arising from unknown causes. The pancreatic hemorrhage may likewise be secondary to inflammation of the pancreas.

PATHOLOGICAL ANATOMY.

The anatomical varieties are the suppurative, hemorrhagic, and gangrenous. The first may be acute, but is usually subacute or chronic. The second is generally peracute or apoplectiform. The gangrenous variety runs an acute course.

Suppurative pancreatitis may result in an evacuation of the abscess into the stomach or duodenum, or it may open into the cavity of the great omentum, which, transformed into a large peritoneal abscess, may, in turn, open into the digestive tract. Pylephlebitis and abscesses of the liver may follow. Disseminated fat-necrosis is comparatively infrequent.

[1] Loc. cit., 299. [2] Loc. cit., 528. [3] Loc. cit., 522.

Hemorrhagic pancreatitis usually proves fatal in from two to four days. The gross lesions are then those of hemorrhage within and near the pancreas, extending into the subperitoneal fat-tissue, perhaps as far as the pelvis. Peripancreatitis may be expected and disseminated fat-necrosis is common.

Gangrenous pancreatitis, although it may be secondary to a perforating inflammation of the gastro-intestinal or biliary tracts, usually results from a hemorrhagic pancreatitis, and proves fatal in the course of a few weeks. The gangrenous processes extend to the parapancreatic tissue, and produce more or less complete sequestration of the pancreas. The peritoneal wall of the omental cavity becomes inflamed, that covering the pancreas may be destroyed, and the sequestrated gland may lie in the omental cavity, soaked in pus, and attached only by a few shreds. Both pus and pancreas may be discharged into the intestine. Splenic thrombophlebitis is not uncommon, but hepatic abscesses are rare. Disseminated fat-necrosis is frequent.

SYMPTOMS.

The common symptoms of acute pancreatitis are sudden, severe, often intense, epigastric pain, without obvious cause, in most cases followed by nausea, vomiting, sensitiveness, and tympanitic swelling of the epigastrium. There is often extreme prostration, frequent collapse, low fever, and a feeble pulse. Obstinate constipation for several days is the rule, but diarrhœa sometimes occurs. If the case does not end fatally in the course of a few days, recovery is possible, or a recurrence of the symptoms in a milder form takes place, and the characteristics of a subacute peritonitis are developed.

DIAGNOSIS.

The symptoms are essentially those of a peritonitis, beginning in the epigastrium and occurring suddenly, during ordinary health, without obvious cause. The diagnosis, therefore, is based on pain, tenderness, and tympany, limited to the region of the pancreas, and on the gradual development of a deep-seated peritonitis in the same place.

DIFFERENTIAL DIAGNOSIS.

The differential diagnosis lies, practically, between an irritant poison, perforation of the digestive or biliary tract, and acute intestinal obstruction.

An irritant poison is excluded by the history of the case and by the examination of the vomit.

Perforating ulcer of the stomach or duodenum is to be excluded by the absence of pain after eating, hemorrhage from the digestive canal, and cachexia. Acute perforation of the transverse colon is rare, and the resulting peritonitis progresses more rapidly and is likely to be general. Perforation from gall-stones is usually preceded by attacks of biliary colic and jaundice, while the seat of the pain is rather in the region of the gall-bladder than in that of the pancreas.

Acute intestinal obstruction is most likely to give rise to doubt. It is to be eliminated by determining, through injection, the patency and capacity of the large intestine; by the rarity, in the epigastrium, of an obstructed small intestine; by the immediate presence of localized tenderness, and by the usual absence of conspicuous general tympany, or limited distention of intestinal coils.

TREATMENT.

It is evident that all treatment, at the outset, can be nothing but palliative. With the formation of pus in the omental cavity comes the opportunity for the surgeon. The possibility of the successful removal of the gangrenous pancreas is suggested by the healthy condition of a patient seventeen years after he had discharged this organ from his bowels.

An unexpectedly early verification of the above conclusions has occurred within the week following the delivery of this lecture.

The case was that of a well-known gentleman of Boston, and presented so fully the symptoms above mentioned, that, when called as consultant, I was able to make a diagnosis of acute pancreatitis, which was eventually substantiated.

The following is a brief summary of the essential features of this case, which will, hereafter, be more fully reported:

The patient was suddenly seized, February 19th, while apparently in his usual good health, with a severe pain and tenderness a short distance above and to the left of the navel. This was followed by vomiting and a certain degree of prostration. The administration of nearly a grain of morphia gave relief. I saw him in the evening, and during the subsequent two days of his life. He died on the third day. The localized pain was more or less constant, with occasional severe twinges, and was also to be elicited by intercostal pressure in the splenic region. The sensation of a constricting band in the epigastric region was likewise mentioned. At the close of the second day the lower abdomen became sensitive in spots. There was vomiting on the first day, but not later, and the bowels were confined. The abdomen was somewhat distended and dull, except in the epigastrium. The pulse was moderately accelerated and the temperature slightly elevated.

The diagnosis lay between acute, mechanical intestinal obstruction, perforative peritonitis, and acute pancreatitis. The majority of the consultants agreed to the first as the most probable condition, and advised a laparotomy, which was performed on the third day. Spots of fat-necrosis were seen in the omentum, but there was no evidence of mechanical obstruction.

At the post-mortem examination the characteristic appearances of hemorrhagic pancreatitis were found, also numerous spots of disseminated fat-necrosis.

ORIGINAL ARTICLES.

THE TREATMENT OF SPASMODIC CROUP WITH OPIUM.[1]

BY ARTHUR V. MEIGS, M.D.,
PHYSICIAN TO THE PENNSYLVANIA AND TO THE CHILDREN'S HOSPITALS.

By the term spasmodic croup I have meant to designate all forms of the disease characterized by the absence of false membrane, whether supposed to be simply spasmodic, inflammatory, or catarrhal,

[1] Read before the Philadelphia County Medical Society, February 27, 1889.

and my desire is to raise the question of what constitutes proper treatment, for the subject is one upon which my own views are very definite. Though the disease only in the rarest instances endangers life, and from that standpoint is not of much consequence, yet it is so very common and causes so much suffering that by proper treatment can in most instances be so readily prevented or relieved, that it is well worthy of our careful attention and consideration. The method of treatment I have always pursued was for many years used by the late Dr. J. Forsyth Meigs, and is described in Meigs and Pepper on *The Diseases of Children.*

It may be premised, in the first place, that in all severe cases the treatment must be begun by the administration of an emetic, and for this purpose, if it be necessary to have a prompt result, nothing will be found better than a teaspoonful of powdered alum mixed with a teaspoonful of syrup of ipecac. If emesis does not occur in ten, or at the outside fifteen, minutes, the dose may be repeated; the second, however, will not often be necessary. This is much better, if it seems desirable that an immediate result be attained, than any other of the emetics—ipecac alone, sulphate of zinc, or any of the preparations containing antimony. The latter I have always looked upon as unnecessary or even dangerous on account of the severity of their effects, though I confess that my personal experience with them has been of the most limited description. I have heard older members of the profession say that in former days, when it was the custom to administer Coxe's hive syrup or antimonial wine in large doses, and to place children in a warm bath, they had frequently seen them die of the complaint, and anyone who has read the letters of Gui Patin, who lived in the reign of Louis XIV., and at a time when almost a crusade was being preached by the physicians of France against the drug on account of the manner in which it was abused, will realize how much mischief it is capable of doing when injudiciously prescribed. For my own part, I am satisfied that any results to be had by its administration in croup can be obtained better, and much more safely, by other means.

The effects of most emetics in children, it must always be remembered, are sooner over and less severe than in adults, and, therefore, their use is often proper when it would be inadvisable to give them to older people. When the question is to be answered, in any case of croup, whether or not to give an emetic, the decision is not so important, for its administration can hardly do any injury unless antimony be used. I have seen a young child, within half an hour after emesis, sit up and eat hungrily. Alum and ipecac, given as has been recommended, act with great promptness, have the most marked effect in relaxing the laryngeal spasm, and, contrary to what is very commonly said of their combined use, produce very little physical exhaustion and relaxation afterward.

When summoned to a case the first question the physician must ask himself and decide is, whether the indications are such as call for the administration of an emetic. This question must be answered by considering the matter of dyspnœa—if there be no dyspnœa emetics seem to me entirely unnecessary, nor do I give one if there be merely a hoarse voice and slightly noisy respiration without real difficulty of breathing. It is only when there is decided obstruction of respiration and retraction of the base of the chest and supra-sternal fossa that emesis is to be at once induced.

If it be decided that an emetic is unnecessary, then something else must be done. It is to be understood that I am now discussing the treatment just as I should if I had been called in in the middle or early part of the night probably, to see a child that had been seized, without previous warning, with a paroxysm of the disease. Having decided that the symptoms were not sufficiently urgent to make the administration of an emetic necessary I should order a dose of laudanum and ipecac, and at the same time give directions for a second dose if the first did not in the course of an hour produce a marked calming effect. By the judicious use of an opiate with ipecac if the case be not so severe as to demand the immediate and somewhat more violent action of an emetic, in my experience the spasm of croup can be better combated than by any other means I have ever tried, and when once a physician and judicious mother have combinedly learned to manage spasmodic croup in this way the disease, except when it occurs in its most violent forms, loses almost all its terrors in a household. Absolute perfection, of course, is not to be attained; and this holds true of our power of judgment of the precise dose of medicine to be given in any particular case of disease. But what is to be aimed at in croup is to give such an amount of laudanum as will produce a moderate but decided soporific effect without narcosis, and ipecac to relax spasm but not nauseate, and especially not to induce emesis. This end would be attained in adults ordinarily by giving about twenty drops of laudanum with fifteen of syrup of ipecac, with directions that a second dose to consist of ten to fifteen drops of laudanum with ten or fifteen of ipecac syrup be given after an hour, or later during the night if it should seem necessary. In children, of course, and it is only in children, practically speaking, that we ever meet the disease, the dose must be made less according to the age. I mention the doses which would be proper for adults merely as illustrating the therapeutic effect that it is my aim to attain, for the amounts of laudanum mentioned could with perfect propriety and safety be given to most adults.

In using this method of treatment of croup it is, of course, a great advantage both to the physician and patient, if the physician already knows from previous experience with the child, the exact quantity of laudanum and ipecac he will have to take to effect the purpose. In administering laudanum to any child that has never previously taken it, no one should ever do otherwise than begin with a minimum dose, and this too at the risk of failing to thoroughly produce an effect, because the event will prove the dose to have been too small for the particular individual. For a child two years old, the initial dose should not be more than two drops of laudanum with ten of ipecac syrup; this to be repeated after an hour, or any time later if necessary. By waiting an hour, a second dose can always, in my experience, be given with entire safety, for if the first has produced no decided effect in that length of time, the second will not produce too much. For an infant of two to six months the first dose, to keep properly within the line of safety, should be half a drop with five or six of ipecac syrup, this to be repeated in an hour if the first be insufficient. In older children the dose must be proportionally larger, and the precise amount to be given is very much a matter of individual judgment, for it is difficult to formulate a precise rule which can be held to rigidly at the moment of emergency.

It is a good plan often, when the case is a severe one, and an emetic has been judged necessary, after its action to wait half an hour, and then give one or two doses of laudanum without ipecac, to induce sleep and relax spasm. This seems often to prevent the recurrence of the attack toward morning, which is likely to take place if the emetic alone be relied upon.

The first night having thus been tided over, a moderate amount of opiate under all ordinary circumstances having been used, and an emetic given if needed, it becomes a question what is to be done next. Is the disease cured, and no further medication required, or does the condition of the child require further attention? Although in the majority of cases of spasmodic croup, by the time morning comes the child will have lost his hoarseness and fever, and will seem often as well as if nothing at all had happened, playing about cheerfully during most of the day if allowed, the disease generally, if left without treatment, returns a second, and even a third night, and the condition of the patient will often be more threatening with the return than it was at the onset. Here then certainly is an opportunity which promises much for preventive medicine, the branch of therapeutics which it is generally thought will effect the best that can ever be done by the science of medicine.

Knowing that the trouble is likely to return, the child should be kept in bed the following day, and given every two hours minute doses of paregoric and ipecac, to which nitre may be added if there be fever. The doses should be so small as to be very gently relaxing, but the amount of opiate too little to induce any sleepiness, and that of ipecac to take away appetite, much less produce any nausea. This result will be most nearly attained in children between two and five years of age by the use of from five to ten drops of paregoric, and about five of ipecac syrup. As much as ten drops of the ipecac, and it is an amount I have very commonly seen given, is sufficient, when administered every two hours, to nauseate many children, and then the remedy becomes worse than the very disease itself, for nothing is so depressing to the general strength and vitality, and natural powers of resistance to disease, as long-continued nausea.

The child having, as already recommended, been kept in bed during the day, when the second night comes laudanum and ipecac should again be given at bedtime, with directions for a second dose if it seems necessary. To say bedtime is, perhaps, not so precise as is to be desired, but the proper time for the first dose is between six and nine in the evening, when the child is tucked in bed to sleep for the night. The doses should be such as already mentioned, unless it be judged that those given the night before were too small, in which case the amount may be increased to such an extent as seems advisable, the previous night's experience having given us a guide to the child's susceptibility to the drugs. During the second day also, the child should almost always be kept in bed, and the minute doses of paregoric and ipecac continued every two hours, and the laudanum with ipecac at bedtime again administered. After the third night, unless the case be one of unusual severity, the cough will become loose, and when this is the case there is no longer any likelihood of a return of spasm. In my own experience it has seldom happened, and then only in cases of great severity, that I have found it necessary to administer an emetic after the first night, though I am sure that if cases be left without treatment, the spasmodic symptoms are apt to be more violent the second or third nights than they were the first. Knowing that the trouble is likely to return, and having learned something of the individual child's susceptibility to opium and ipecac, it is much easier to prescribe, both with safety and confidence in ourselves, such a dose as will prevent the return of violent spasm, and this, it should be thoroughly understood, does not require the administration of any large dose of laudanum. As already stated, the effort should be to give such a dose as will produce an effect parallel to that of twenty drops of laudanum upon an average adult,

and it is always both safer and better to err upon the side of giving too little than too much. One difficulty that very commonly has to be met, is that on the day following an attack, if the child be at all feverish, the appetite will generally be very poor, or abolished, and this will naturally be attributed by anxious mothers to the medicine that was given; but if it be explained that it is due to the cold and the accompanying fever, there will usually be no trouble in having the treatment continued.

The treatment of the disease after the spasmodic symptoms have passed off it is not necessary for me here to discuss, for it must be that of coryza, or bronchitis, or both, according as the inflammatory process which had its origin in the larynx travels upward or downward, or in both directions, for it is sufficiently well known that an attack of spasmodic croup is almost always followed by, or perhaps more properly is, the first symptom of a cold of some sort.

It will not be amiss for me now to give a few quotations to show that I am not alone in the opinion expressed in regard both to the great value of opium in children's diseases and its entire safety when properly used.

In Meigs and Pepper on *The Diseases of Children*, as I have already said, opium is highly recommended as most valuable in cases of spasmodic laryngitis.

The following quotation is taken from West on *The Diseases of Children*, page 31:

"A third great remedy in the diseases of early life is *opium* in its various preparations; and with it may be classed, though separated by a wide interval, other sedatives. . . . . Perhaps no remedies are so often needed in the diseases of early life as sedatives, for at no other age is the nervous system so easily disturbed. At the same time, the susceptibility to the action of narcotics and sedatives is so remarkable, and the evils which result from their unnecessary employment, or from their administration in excessive doses, are so serious, that some practitioners altogether abstain from their use. To do so, however, is to deprive ourselves of one of the most important classes of remedies, and of one for which no substitute can be devised."

Goodhart, on *The Diseases of Children* (edited by Starr), page 25, expresses the view that the dangers of the administration of opium to children are overestimated, but says that the initial dose should always be a small one.

Eustace Smith, in his book on *Disease in Children*, page 19, says:

"Opium, it is well known, should be given with caution. The remedy is, however, of extreme value, and if care be taken to begin with only a small quantity, and to postpone a second dose until the effect of the first has been ascertained, no ill effects can possibly be produced by the narcotic."

Again, in his *Clinical Studies of Disease in Children*, the same author, in speaking of the use of the drug, at page 18, says:

"It is, however, a medicine which is of especial value in the treatment of the diseases of infancy, and may be given without fear if care be taken not to repeat the dose too frequently."

Having now described the method of treatment which in my hands has proved so efficacious, and up to the present time so free from danger, and by the above quotations having shown that some of the most highly considered and widely quoted authorities are of the same opinion in regard to the use of opium that I have myself expressed, I have only two things to add:

First, my opinion that an unusual susceptibility to the influence of the drug in children is not common, no more so than it is in adults, among whom, when it exists, it is called an idiosyncrasy, so rare is it. The reason that the use of the drug has had a bad name among physicians is because the initial dose given has so often been too great and not because the idiosyncrasy is common. The truth of this statement is borne out by the fact that so many of the authorities upon questions of diseases of children, and presumably the acknowledged authorities, are those who have had the largest experience and are, therefore, best qualified to judge, recommend the administration of opium as both valuable and safe. Most important of all, perhaps, for us to remember in coming to a decision whether or not we shall deny ourselves the use of the drug in treating the diseases of childhood, is the fact that even in those rare instances in which the idiosyncrasy does exist it is almost impossible, if the initial dose given be a sufficiently small one, that it should cause death. The usual result is that the child is slightly narcotized—made to sleep somewhat heavily—and the parents and physician are frightened lest worse should come of it. Shall we on this account deny our patients the many advantages to be derived from the administration of a drug the use of which will only be dangerous owing to our own lack of care?

Finally, it is quite incomprehensible to me why the use of opium should be decried when children, even the youngest, are freely given many other drugs which are confessedly much more dangerous, and the effects of which it is much more difficult to observe and control—as, for instance, chloral, aconite, antimony, arsenic, and belladonna. The last mentioned of these, belladonna, is a drug of which common report says children can take much larger doses relatively than adults, and yet it is the only one with which, up to the present time, I have ever in my own practice had any untoward effects among children. Some years ago I prescribed a cough medicine containing alum and half a drop of tincture of belladonna to the dose for two children aged respectively about three and five years. Two or three doses of this medicine were to be given an hour or more apart; the first when they went to bed and the others afterward if they did not sleep. In

the middle of the night I was summoned to the house, to find that two doses had been given to each child, and that the *younger* was in a sound sleep, more quiet and natural than she had enjoyed for many nights owing to the troublesome cough that had existed, while the *older* child was sitting up in bed wide-awake, with the pupils somewhat dilated, and the chest covered with a red rash. After watching the case for a time, I assured the mother that no harm would come of it, and the next day the child was as well as ever. This certainly was a marked instance of idiosyncrasy, for in the younger child the therapeutic effect was exactly what had been sought for, while in the older I had to deal with a mild case of belladonna poisoning. It was also a marked instance of what generally happens, if perchance a properly small dose of any powerful drug is given to a person who proves unusually susceptible to its influence, and it is that the effects are much greater than was desired, but in nowise dangerous and hardly very alarming.

It is unlikely that by my imperfect exposition of my views upon this subject I shall have persuaded anyone whose mind was already made up to the contrary, to come over to my side of the question, though it may be perhaps that those already of my opinion or in doubt about the matter, will be strengthened to pursue the method of treatment more boldly, or to try it. It is certain, however, that discussion of a subject has its good effects by causing opinion to crystallize more and more in the direction of the truth, and in this manner, at least, I trust my efforts will not have been entirely in vain.

THE PREVENTION AND TREATMENT OF CRURAL ADDUCTION.[1]

By HENRY LING TAYLOR, M.D.,
of New York City.

Most of the moderately advanced cases of hip disease that I have examined have presented an adducted thigh; and this is equally true of those who have first applied after the cure of their disease. Drs. Shaffer and Lovett in their admirable investigation of the "Ultimate Results of the Mechanical Treatment of Hip-joint Disease"[2] found 10° to 30° adduction in nearly one-half (11 out of 24) of the cured cases examined to determine this point; the report included only those cases treated at the New York Orthopædic Dispensary and Hospital who had been discharged cured not less than four years previously. There is no doubt that the proportion of adducted thighs in old cases cured by less thorough methods is considerably greater. Typically deformed old hip cases form one of the commonest and worst classes of the permanently crippled, and as seen on our streets, more than three-quarters show an adduction easily observable in the carriage of the body; in addition the thigh is usually flexed and inverted, and the deformity and disability are sometimes so great as to doom the sufferer to crutches for life. Take a few examples of the condition of the hip-joint in cured cases that had been treated by methods other than properly applied traction.

Case I.—Girl, twelve years old, first seen in 1880, having been free from symptoms of disease for five years. She had had right hip disease at five, lasting a year and a half. An abscess appeared in 1874, which discharged four months. Plaster bandage, short splint, and weight and pulley had been used, followed by crutches for two years; since then the patient had used one crutch. Examination showed a stiff hip, adducted about thirty degrees and considerably flexed and inverted. She wore a steel patten three inches high. This girl died of phthisis five years later.

Case II.—Girl, eighteen, seen in 1880. She had had double hip disease in childhood. There were eight large cicatrices about the hip; none had discharged for two years. Both thighs were ankylosed and adducted. The right was drawn in the most, and it was also flexed, so that the popliteal space of the right limb came directly over the inner condyle of the left femur; the legs were crossed bringing the inner borders of the feet to the outside. The inner (small toe) edges were six inches apart. The patient walked from the knees, which were loose.

Case III.—Male, eighteen, seen in 1883. Left hip disease in 1880. Leg and pelvis incased in plaster sixty weeks. Had been walking about and considered his hip well. There was but a trace of motion and the thigh was flexed and strongly adducted. When seen he was laid up with an acute abscess, probably extra-articular.

Case IV.—Gentleman, fifty years old, seen in 1885. Right hip disease when about four years old, abscesses followed and discharged two or three years. Patient had gone around all his life with leg drawn up and in, until a year before, when, owing to appearance of pain and increase of disability, he took a crutch, which he had used since. Right trochanter was two inches above Nélaton's line. Thigh was flexed and extremely adducted. There was pain in the hip, though he bore no weight on it. He wore about five inches extra sole.

Case V.—Gentleman, about thirty-two, seen in 1887. Right hip disease at four years, no abscess. Was walking in a year. Ankylosis with considerable flexion and adduction. Walked very fairly.

Case VI.—A lady, about twenty-seven, seen in 1887. Disease of left hip-joint at three years. Treated by weight and pulley with plasters below the knee. Disease, including a relapse, lasted five or six years, most of which time she was off her feet; the later part of the time she walked on crutches. She had a flail-knee from improper application of the traction. Extensive hip motion, but there was 15° permanent adduction, and two and a half inches

[2] New York Medical Journal, May 21, 1887.

shortening. Walked with cane short distances only, and disability was increasing.

This recital might be considerably prolonged, but perhaps enough has been said to give an idea of the condition in which patients are frequently left after the cure of their disease, when imperfect methods have been employed.

When a patient has suffered from hip disease, which was not arrested in the earliest stage, but has gone on to destroy portions of the joint tissues, it is still possible for him to make a recovery which will be more or less perfect according to the protection afforded by the treatment. The ulcers and erosions in the joint may heal and be repaired by bone and cicatricial tissue, rough places may be somewhat smoothed off, sinuses and abscesses dried up, and the joint left free from disease. Even when this favorable result takes place (and we regularly expect it under the protective plan of treatment) the patient recovers with a more or less useful, but still a functionally imperfect joint presenting one or more of the following conditions:

1. Impairment or loss of hip motion.
2. Joint instability.
3. Shortening and atrophy of the affected limb.
4. Malposition of the thigh, which may be permanently adducted, or rarely abducted, with flexion, and often with inversion or eversion.

Of these regular sequelæ of the disease the malpositions are certainly the most serious as regards the comfort of the patient and the usefulness of the limb, and probably the most preventable and curable. I have never seen a case of ankylosis in good position of one hip where the locomotion was not excellent, and I have seen several ankylosed cases where the abnormality of gait was so slight as easily to escape notice, owing to the nearly perfect compensation at the lumbar spine, the knee, and the opposite hip.

Take as illustration CASE VII., a young man of nineteen, whom I examined in 1885. He had had left hip disease at two years, and had been treated on the protective plan by Dr. C. Fayette Taylor for several years. He had had an abscess which had closed years before. Home coöperation had not been of the best, but he got well with ankylosis in perfect position. In 1885, nine years after leaving off treatment, he was in rugged health and walked freely without support, and with a scarcely perceptible limp. The thigh was ankylosed, moderately flexed, parallel to the median line, and the two legs were equal in length.

Last year I examined a former patient, a lady (CASE VIII.) twenty-eight years old, whose left hip became affected in 1881. She was treated by recumbency with weight and pulley for a year and a half without benefit. At the end of that time she came under my care; the thigh was slightly flexed and considerably adducted and there was deep fluctuation in front of the hip. The adduction and fluctuation disappeared under protective treatment and she recovered with ankylosis in perfect position. At the last examination a year after her discharge, there was very slight flexion of the thigh, which was parallel to the median line. The affected limb measured one-quarter inch longer than its mate, as I convinced myself by repeated trials. Her health was robust, she walked freely without support of any kind and with a hardly perceptible abnormality.

Shortening after hip disease can be compensated, and, unless excessive, does not compromise the usefulness of the limb even when added to ankylosis. When a joint is so much eroded and relaxed as to afford no firm bearing, the limb may be less useful and the gait insecure, but this condition is not very common at the hip, at least in a disabling degree, except after excision. On the other hand, considerable flexion or abduction, or a moderate amount of adduction with or without actual shortening, seriously interferes with bodily equipose and harmonious muscular action, and tends to render the carriage so awkward and the gait so limping and difficult, that both the endurance and the locomotor capacity of the patient are much curtailed. Some flexion nearly always remains, and a moderate amount is favorable where stiffness exists, since it more readily than any other position permits both standing and sitting. Slight abduction of the thigh is also favorable, as it prevents crowding of the thighs and compensates shortening to a certain extent, but is not usually attained except as the direct result of special management.

Eversion ordinarily goes with abduction and inversion with adduction, but the association may be reversed. They are not usually very disabling in themselves.

Adduction is the worst of the malpositions and is bad in any degree. The pelvis is tilted up on the affected side, increasing practical shortening and bending the lumbar spine laterally in order to bring the limbs vertically parallel, balance is deranged, and spontaneous movements of the body and limbs are adjusted to an awkward position. Every muscle is used at a disadvantage, there is undue strain on the knee and back; the thighs are crowded together, and the patient's general health and vigor frequently suffer from the severe strain of movements performed under unnatural and hampering conditions.

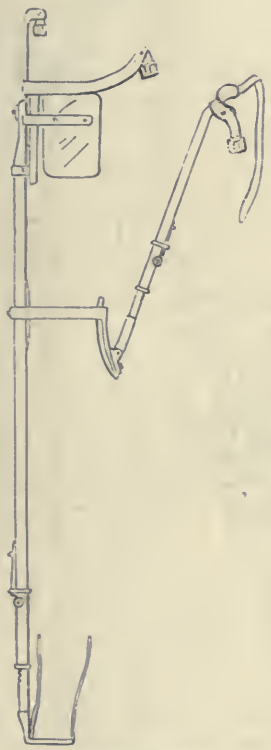
I have seen several cases where no cause other than crural adduction could be discovered for extreme rotary lateral curvature of the spine.

Adduction of the thigh from muscular spasm in the acute or progressive stages of hip disease is in some measure an index of articular irritation and in most instances readily yields to the protective traction required at that period, which can be adequately furnished by the long hip splint. The trac-

tion is always exerted in the line of the deformity, and is regularly combined with recumbency and the weight and pulley during the first few weeks of treatment. The leg falls easily into position as the spasm relaxes. Later in the treatment, if signs of irritation or tendency to deformity develop, the patient is again put to bed for a few weeks and the stretching repeated. Many cases treated from the early stages on this plan progress uninterruptedly toward recovery without the occurrence of deformity. In the rare cases in which properly applied traction fails to relieve the muscular spasm owing to products of inflammation confined in the joint, the tendency to adduction may continue until this is relieved.

Persistent adduction, especially in the recovering stages, or after the cure of the disease, whether from the severity of inflammatory irritation, subluxation of the eroded femoral head, neglect of proper treatment in the beginning, or from other causes, often requires special means to overcome it. The long hip-band carrying two perineal straps and the abduction screw were formerly employed for this object. With the idea of securing greater simplicity

FIG. 1.

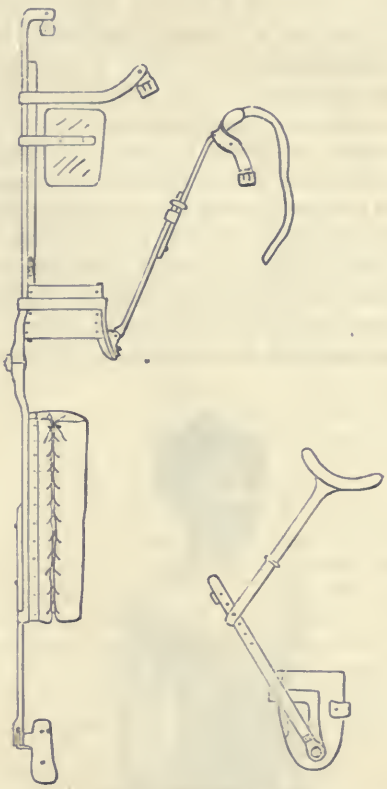


Traction splint.

and solidity of construction as well as greater precision of action the hip-band and abduction screw were discarded by Dr. Taylor some twelve years ago, and the traction splint used without a joint, the single perineal strap being carried on the anterior and posterior ends or horns of a properly curved stiff steel bar riveted to the side plate of the apparatus. This splint (Fig. 1 shows front view with ratchet abduction crutch added) furnishes any desired amount of traction, and limits though it does not abolish motion at the hip-joint; it has given great satisfaction in practice.

In the regressive and recovering stage after the subsidence of inflammation, we have found great advantage in the use of the jointed supporting splint (Dows',[1]

FIG. 2.



Jointed supporting splint.

Fig. 2, front view with toggle abduction crutch added) which enables the patient to use the joint and limb without subjecting it to injurious pressure.

When a direct abducting force is required we add to the traction splint or Dows' an abduction crutch or attachment (shown enlarged at right of Fig. 2). This consists in a double (compound) steel bar acting as a toggle-joint, the lower end of which is pivoted to the knee-plate of the apparatus, and the upper end terminating in a properly curved steel band covered with hard rubber and accurately fitted to the ischial fold opposite the affected hip. The length of the bar can be varied by shifting the pin jointing its two halves. When the toggle-joint acts, a direct abducting force is put upon the

[1] In use sixteen or seventeen years, shown at the Amer. Orthopædic Association Meeting, Washington, September, 1888. Its use as a supporting apparatus in weak joints after the excision of the hip has been suggested.

affected leg. This apparatus serves for comparatively mild cases or as a retaining apparatus after abduction has been produced.

For severe and long-standing cases the patient is put to bed with the traction splint applied, and a ratchet crutch (shown in Fig. 1), pivoted to the inner knee-plate of the apparatus, is applied, by means of which a progressively modified abducting force can be applied to the thigh. Usually a few weeks in bed with the ratchet abduction crutch, the leg being in a sling and extra weight attached to the traction splint, will cause exceedingly obstinate and long-standing cases to yield, as has been practically demonstrated several scores of times. On getting up, if the hip still requires protection, the traction splint or Dows' is used according to the special indications presented, and the toggle-joint abduction crutch is added as a retaining appliance, when necessary, since the ratchet abduction crutch is not conveniently worn except during recumbency.

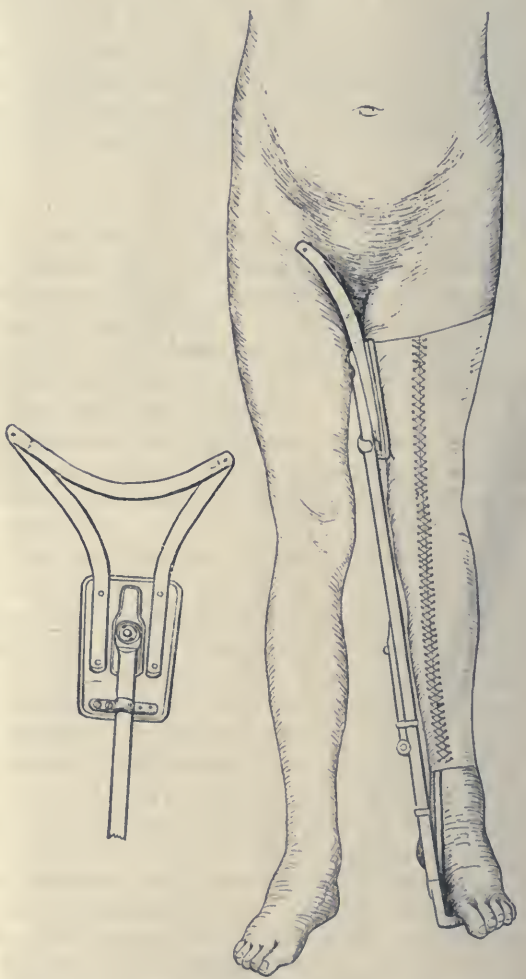
If no disease is present, the patient on getting up may or may not require retaining apparatus. If one is necessary to hold the thigh properly abducted for a longer or shorter period, the jointed supporting splint with toggle-joint abducting attachment, but without horns or perineal strap, often answers the purpose, but a more efficient apparatus is the median abduction splint (Fig. 3). It consists of an apparatus jointed at the knee and provided with a slip-joint at the ankle, the supporting bars being on the inside of the leg. Since it is not intended for hip protection, but merely as a retentive apparatus, with provision for knee protection, it has no perineal strap. It is secured by plaster to the inside of the thigh, as is the Dows', and has pivoted to the knee-joint the toggle abduction attachment. This leaves nothing to be desired as an abduction retainer, and as it can be worn indefinitely without discomfort, patient and surgeon are independent of time.

It would seem that the apparatus described, which have been in use more than a dozen years, met every indication in connection with the prevention and cure of the adducted position, but in dealing with a few particularly intractable cases, especially some due to causes other than hip disease, such as fracture of the femoral neck, old dislocations of the hip, etc.,

FIG. 3.

Median abduction splint.

FIG. 4.[1]



Long median abduction splint.

still more powerful means have been found desirable, and Dr. Taylor devised the long median abduction apparatus (Fig. 4). By means of this apparatus we can apply to the limb a very powerful, direct-acting abducting force, capable of exact regulation; and, after four years' experience in its use, I can report that from a few days to a few weeks have been sufficient to abduct the limb in the considerable number of cases in which I have used it. I relate a few cases illustrating the methods described.

CASE IX.—A stout boy of fifteen, recently discharged cured, had right hip disease at five years of age. He has had no disease for some time, but his treatment was prolonged by the strong and persistent adduction, which necessitated a week's stretching, two or three times repeated, with the long median abduction splint and the wearing of the jointed median splint as a retaining apparatus. The tendency to adduction was completely overcome, and the leg is now slightly abducted and flexed, with two inches shortening and a few degrees of motion. There never was an abscess; the boy's health is robust. He has left off all support and walks well.

CASE VIII., already related, came with a nearly stiff joint and about ten degrees of persistent adduction, which was observed after her long confinement in bed with the weight and pulley. The adduction was overcome by the use of the long traction splint, with abduction crutch worn in bed. She did well, but a year later the hip was still stiffer, and there was some recurrence of the adduction, which was overcome with the long median splint in about a week. On getting up she wore the Dows' splint with toggle abduction crutch, and was cured with ankylosis and perfect position (the limb slightly abducted).

CASE VI., already mentioned, is now under treatment for the adduction, although it is twenty years since her joint was cured. I applied the long traction splint with ratchet abduction crutch, and have attached adhesive plasters only above the knee, and in such a way that it is completely protected. The leg was quite resisting, but yielded to a few weeks' traction, and was thrown into abduction, so that I was able to remove three-fourths of an inch from the high shoe she was wearing. I am now making a jointed median retaining splint for her.

CASE X.—In a boy of thirteen, whose left hip was dislocated at birth, causing flexion and extreme adduction with great disability, complicated by extreme secondary rotary lateral curvature of the spine, I have been able to overcome the adduction whenever he took a few days in bed with the long median abduction splint. There has been difficulty in holding it owing to the lateral curvature, but the deformity has been greatly reduced.

CASE XI.—A lady of over fifty came recently with a severe senile coxitis with stiffness and over fifteen degrees permanent adduction. The deformity was overcome by a month's application of the long median abduction splint. There is also difficulty in this case, from special complications, in retaining the corrected position, and here, as in the preceding case, I still apply the long median traction splint at night, fastening it to the lower end of the supporting splint, with gratifying results.

CASE XII.—A girl of twenty applied at the N. Y. Orthopædic Dispensary and Hospital in 1874, walking on crutches, to which she had been confined ever since her trouble began. She had had left hip disease at ten, with very extensive abscesses, which discharged about two years. When seen in 1874 the thigh was extremely flexed, and Dr. Newton M. Shaffer, who remembers the case very well, says there was adduction and not much motion; the record is defective on these points. She was treated with the traction splint and in five weeks was able to walk about without her crutches; the shortening was two and a half inches. In a few months she left off the brace, but in 1877 suppuration recurred at the old site, lasting six months, and a supporting apparatus with abduction crutch was applied in 1878. She has been in the habit of reporting to us once or twice a year since then, and has been reluctant to give up her brace, though she has been well for many years. I took off the abduction piece two and a half years ago, and the entire brace six weeks ago. For over eleven years there has been no suppuration or sign of hip trouble. There is now extensive motion in every direction, no deformity, the thigh being slightly abducted; there is three inches shortening; she is in good health and walks readily without support and but moderate limp. This patient was shown at the meeting of the Section.

CASE XIII.—Girl, ten years old. Left hip disease at age of three. Came under treatment six months later and was one of those exceptional cases not readily relaxed by traction. Abscesses formed in Nov. 1884, and discharged for a year. Three years ago suppuration ceased and the patient has been free from active disease, in good health and walking nicely, but with rather persistent adduction, which has been treated with the median abduction splint (Fig. 3). This patient was exhibited to the Section to show the apparatus in action.

CASE XIV.[1]—A gentleman reported in 1883 with an adduction of the right leg of thirty years' standing, from an injury to the hip. When seen the adduction amounted to about twenty degrees, and could not be diminished by manual force; together with the actual shortening it necessitated an extra sole three inches and three-quarters in thickness. The adduction was completely overcome in less than two weeks, the legs restored to vertical parallelism, and the sole reduced to one inch and three-quarters, which represented the actual shortening. Progression was rendered very much easier, and the patient did not complain of pain or fatigue as he had done. The position was easily maintained by the jointed median splint. The apparatus used in this case to overcome the deformity was the long traction splint with ratchet abduction attachment (Fig. 1).

There is a large field for brilliant results in old cases of joint disease or joint injury which have long

[1] Reported in the N. Y. Med. Journ., Nov. 19, 1887.

since been pronounced cured, but whose limbs have been left in such faulty position that they are deprived in great part of their legitimate use.

With the improved methods described, the distressing and disabling deformity of crural adduction has ceased to be, in the large majority of cases, the formidable matter that it has been, and I believe that where proper attention can be secured permanent adduction need never occur, and that when this condition has supervened it can be safely and quickly removed with scarcely any discomfort to the patient, and without resort to the knife or chisel in nearly all conditions except bony ankylosis.

Mr. Christopher Heath has said:[1] "Our duties in a case of fracture should be considered to end, not when the bone is found to be united, but only when the functions of the limb have been as far as possible restored." These words apply with ringing emphasis to the treatment of joint disease.

201 WEST FIFTY-FOURTH STREET.

AN UNUSUAL OSSEOUS GROWTH IN THE FALX CEREBRI.

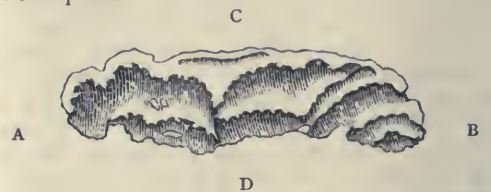
BY HALDOR SNEVE, M.D.,
ASSISTANT PHYSICIAN AT THE DAYTON ASYLUM FOR THE INSANE.

IN making a post-mortem on a colored patient who died in this institution January 3, 1889, I found the anatomical curiosity described below.

The patient, Turner Graham, was admitted May 15, 1888, suffering with *mania* of one year's duration, æt. forty-five years, servant by occupation, very intemperate, of limited education, and unknown heredity. On entrance physical examination showed man to be of little above the medium height, somewhat emaciated, head well formed for one of his race, old syphilitic cicatrices on legs, some consolidation at apex of left lung, heart sounds normal, slight cough and expectoration, and urine normal.

Patient emaciated rapidly, although he ate ravenously; cough and expectoration increased; and during the last few months of his life he had œdema of feet and ankles, although chemical and microscopical examination of the urine revealed nothing abnormal. He passed into *secondary dementia*, became filthy in his habits, and finally died of pulmonary tuberculosis, about eight months after admission.

AUTOPSY.—On removing calvaria, the bones of the skull were seen to be greatly thickened, measuring three-fourths of an inch at the occipital bone. *Dura mater* adherent to calvaria at its convexity, apparently healthy; considerable sub-dural fluid. *Pia mater* stripped readily from the convolutions. Brain very moist and unusually soft; section revealed no macroscopical evidences of disease. Passing my fingers along the great longitudinal fissure, they encountered a hard substance at its anterior part, enclosed within the falx cerebri; believing at first that what I felt was a calcareous deposit, I examined carefully all the vessels of the brain, but found no calcareous matter in the walls of any of them. All the tissues surrounding the substance were next carefully examined but they all looked healthy, no adhesions or thickenings indicating a preëxisting inflammation. The bone (as it subsequently proved to be) was enclosed within two thin layers of the falx cerebri; its long axis parallel with the long axis of the latter, and following the general curve of the falx. The posterior extremity considerably elevated above its anterior. The anterior point of the bone was distant about one inch from the anterior point of the cerebral hemispheres, and occupied a position about midway between the upper and lower edges of the falx. The wood-cut below represents the exact size of the specimen, and shows its left surface, the elevations and depressions corresponding accurately to similar ones on the internal surface of the left hemisphere.



A, represents anterior point; B, the posterior; C, the upper edge; and D, the lower.

The falx supplied the place of periosteum. At its thickest part, the bone is 6.25 mm. in thickness. Weight is 1.2 gm.

Both surfaces of the specimen exceedingly rough, and traversed by furrows and depressions; the surface of the falx being finely granular.

A section of the bone showed the interior to be cancellated, Haversian spaces rather small, and bony spiculæ passing in different directions without any apparent regularity or arrangement.

A section of the thin layer of compact substance under the microscope shows lacunæ and Haversian canals as in adult human bone. This bone was undoubtedly developed in the falx and in all probability was congenital. Its rough, excavated appearance would seem to indicate that it was being slowly absorbed, and at one time probably was of larger size. That it had any connection with or influence on the patient's insanity, is highly improbable. In the literature at my disposal, I can find no record of a similar osseous growth occurring in the falx.

REPORTS OF SEVERAL CASES OF ANGIO-NEUROTIC ŒDEMA.[1]

BY ALLEN J. SMITH, M.D.,
ASSISTANT DEMONSTRATOR OF PATHOLOGY IN THE UNIVERSITY OF PENNA.

THE literature of this peculiar condition is singularly meagre, and in searching the journals and works within my reach I have been unable to find any other references than those detailed in the paper presented to this Society some months ago by Dr. William Osler, upon an hereditary form of the disease. Pre-

[1] Read before the Philadelphia Neurological Society, January 29, 1889.

senting much the general characteristics of an extensive form of urticaria, and in its general aspect resembling this affection in most particulars, it has, by a number of writers, been referred to similar, but more extended, anatomical changes of structure in the papillary layer of the skin, with some neurotic etiological factor at the basis. This view, accepted by most dermatologists in the case of the urticarial wheals, includes an inflammatory condition. There is supposed to occur first a hyperæmia of the capillary vessels of the papilla, followed by the escape of a proportion of the white blood-corpuscles and serum from the vascular lumena, and grouping of these ele ments about the vessel walls, with gradual occlusion. In this manner the papilla is enlarged enormously, the blood is excluded from its structure; and macroscopically it shows itself as a white, bloodless papule, about whose base is a zone of hyperæmia, and covered by an epidermis shining and stretched from pressure from beneath. Section of the papular eruption in rabbits caused by the irritation of nettles, according to Neumann, confirms this view, and shows, moreover, a similar condition of the lymphatic tracts, the lymph corpuscles banked about the narrowed vessel, and aiding in the general swelling of the part. A number of such papillary swellings coalesce to the formation of a wheal, and the general mechanism is extended to explain the more widely swollen areas in this condition of acute, circumscribed œdema.

That such a condition, at times, does obtain is quite probable. The following case was seen some months ago in the southwestern district of the Philadelphia Dispensary:

A young woman asked relief for a recurring œdema of her face about the nose and eyes. Five years previously she had had a severe facial erysipelas, and since then each year at some time during the cold months, and each time preceded or associated with an acute nasal catarrhal inflammation, the tissues about the nose and eyes became swollen into deformity. The attack in which I saw her was the fourth. There was not the usual pitting upon pressure, the swelling being limited to the dermal structure and invading the subcutaneous cellular tissue; there was no pain, and no discomfort save the marked itching at times, which was readily allayed by sedative applications, as carbolized solutions. The skin was tense and shining, and the whole swollen area of the ordinary waxy hue of œdema. These attacks lasted for several days each, and disappeared as rapidly as they appeared. The nasal catarrh, however, was not especially influenced by the disappearance of the œdema, and each time continued for some days or weeks longer. No other parts of the body were in any way affected, and had not been in any of the attacks, and the disturbance was distinctly localized to the parts described.

In such a case, in which little or no neurotic element can be called in as an etiological factor, the whole process is explained by the ready extension of the nasal and conjunctival trouble to the adjacent dermal structures, whose power of resistance had suffered distinct shock, and probable deterioration, in the erysipelatous attack years before; except possibly the rapid and complete disappearance of the results of the process before the cessation of the inflammation from the primary site in the nasal mucous membrane. This might, however, be accounted for by a continuation of the catarrh for a longer time than the dermal symptoms because of the irritation from the passage of air and irritants over the inflamed membrane, the dermal being both of a slighter character and being more protected from agencies which would cause its continuation.

Another instance more closely connected with the subject in hand, perhaps, occurred in the case of a woman about the period of the menopause, with marked neurotic tendencies, during my service as a district physician in the above-named dispensary.

This woman first called medical aid for the relief of symptoms of muscular rheumatism, which yielded readily to salicylates. Following the administration of this drug some days, an attack of gastritis set in, and for a number of weeks the ingestion of any heavy food, or of fish, or certain vegetables, was invariably followed by a widespread eruption of urticaria, lasting for a few hours and then disappearing without further care. In several of these attacks there was associated facial swelling, especially marked about the eyes and cheeks, of transient duration, and only noticed because of its disfigurement and the persistent itching sensations attending both this uniform swelling and the more discrete papular and wheal-like eruption over the rest of the body. The swelling here was not so marked as in the first case, and presented to the touch a hard, firm sensation directly in the dermal tissues and not beneath. The surface here was not so completely bloodless as in the ordinary urticarial eruptions, but presented a somewhat mottled appearance—suggesting the probable method of origin from coalescence of a number of the larger wheals. These swellings ordinarily lasted a less time than the wheals elsewhere on the patient's person, and after leaving there remained for a time a slight burning sensation, and the parts became flushed. There was no renal disease noted from the urinary examination; and the only other symptom noted at the time was the passage of bright blood occasionally from the intestines. The origin of this was probably hemorrhoidal, but on account of the refusal of the woman no examination could be made.

To this same class in which are associated inflammatory conditions, might, with propriety, be relegated the case of a young man, a druggist, who incidentally mentioned the fact that at the outbreak of every cold—especially nasal—his under lip and the lobe of the left ear invariably became swollen, hot, and uncomfortable—lasting for a few hours or a day and then disappearing. The swelling is spe-

cially marked in the lip on the same side as the ear, and the relation between these two foci of œdema and the catarrhal inflammation probably depends to some extent upon the distribution of branches of the facial and auricular nerves, or the fifth nerve.

Whether this condition of an extension of some inflammatory influence—perhaps latent to outward observation—is invariably present in cases of acute circumscribed œdema is questionable; and unless, as suggested by this last case, this inflammatory influence be usually transferred through nervous activity, or a secondary focus of hyperæmia with resultant œdema be produced by nervous reflex, another condition must be invoked for further explanation. The fact that in the ordinary cases of this affection, whether marked by hereditary taint or not, the symptoms almost always follow the ingestion of some substance of indigestible nature would suggest the first idea, although it would not preclude the possibility of some other result than an inflammatory one from the nervous reflex from the focus of irritation.

The following case strongly suggests the possibility of this condition, consisting of a non-inflammatory origin and course throughout, depending upon the association of an hereditary tendency and general malnutrition as strongly predisposing causes and the occurrence of some unobserved exciting agency—in one instance ascribed by the patient to a psychical or moral agency.

The patient at the time of the first attack was about sixteen or eighteen years of age, in poor general health, anæmic and tending toward chlorosis. The attacks recurred without apparent cause or warning several times a year until she was twenty-two years old, a short while before marriage. The swelling was usually confined to the face, but on several occasions one or both arms partook in the process. Preceding the swelling there was a marked itching from urticaria, which, however, always disappeared before the œdema reached its maximum. There were no painful symptoms manifest, the only discomfort arising from the feeling of fulness and tensity of the parts. The duration of the attacks varied from a few hours to a day. In no way could indiscretions in diet be associated causatively with the attack. At the time of the last attack she was placed in the hands of one of the physicians of the University, who recognized the influence of the underlying chlorotic dyscrasia, placed her upon a ferruginous treatment and a carefully systematized mode of life, following which there resulted an almost immediate general improvement and since which there has been no recurrence of the œdema.

Shortly after she married, and in the four years of her married life she has borne three children, the older two healthy and robust, the third more or less sickly; has had a miscarriage last January and is now pregnant a fifth time. Notwithstanding the notable drain upon her system from prolific childbirth in the history she has given, her health has steadily improved. At present she is a well-nourished and well-developed woman, of slight stature, medium clear complexion, nervous temperament and apparently strong constitution. The father of this woman, a small, compactly built man, also neurotic, in early middle life had been subject to the same peculiar affection, manifesting itself in a similar manner. No record of further hereditary taint could be obtained; and the children of my patient are entirely without symptoms of a like nature.

It is entirely improbable that sufficient inflammatory action should be aroused to give rise to such marked and general symptoms without undoubted evidence of its presence; and the apparently causeless nature of the malady, the absence of digestive symptoms, would suggest a central and wide-reaching influence in their production. As an explanation of these phenomena, the occurrence of another instance which I shall presently narrate, has suggested the possibility of the existence of an acute lymphangioma, depending upon disturbances of the lymphatic vasomotor nervous influences. The proof of such a theory I acknowledge I cannot offer, but the appearances of the following case seem to agree with the supposition, and it is not impossible that others of the cases may be accounted for by the hypothesis.

Miss M., aged twenty-five years, one day in the early part of last November, while walking in the street, felt a peculiar stinging sensation throughout the right side of her body, and before she could reach her home, some squares distant, began to swell uniformly over this part of her person. The evening before she had eaten raw chestnuts and had had celery at her dinner. She was born with a large birth-mark over her entire right side; and this side has always been rather below the left in condition of nourishment, the limb and arm smaller and very slightly shorter, the mammary gland smaller, and the whole side more apt to become cold upon exposure or to feel fatigued upon exercise. The first attack occurred two years ago, and the one in which I found her was the third or fourth since then. The entire right side was swollen to marked disfigurement, the eye almost closed, and the mouth drawn because of the swelling to the affected side. The arm and limb were both markedly enlarged, and the whole surface hard and smooth, with no irregularities of swelling. The color was that which would be given by a thin coating of white powder over a dusky red. There was no heat in the swollen parts and no pitting upon pressure. There was no pain from the swelling, but during the attack several times she complained of slight colicky pains; the only sensation over the affected part was one of tenseness and fulness, with occasionally some itching. This condition lasted several days, and then gradually disappeared.

Examination of a bit of the fluid which came from pricking the swollen part, showed it to contain a large proportion of leucocytes, and the rest was clear serum; the urine during the attack presented no special peculiarities under the microscope or

upon a routine chemical examination. The tongue appeared slightly swollen, but no unilateral anomaly could be detected in the coating or color. The case has no hereditary history, has always enjoyed fair health until the last few years, since when she has grown to be regarded as delicate. Within the last three years she has twice fainted—both times in church—and has shown a number of hysterical traits.

This last case would suggest, from the color of the affected portions and from the absence of heat, the probability of the presence of another factor than one of a simply intensified angioma of the affected side. The absence of pitting on pressure and the rapidity of disappearance would appear to preclude the idea of serous cellular effusion (of inflammatory origin) with subsequent resorption, and the general conformity of the swollen portions with the angiomatous area of the right side would suggest a possibility of a similar condition of the lymph-vessels, due perhaps to the same altered innervation. Such an hypothesis, too, could, without undue strain, be brought to bear on the case of hereditary tendency, in whom there was no irritant cause apparent whatever; and it might with equal propriety, too, be extended to the case of œdema of the lip and lobe of the ear.

Fully appreciating the weak points in this train of arguments I have outlined, and unable from evident reasons to verify or deny my position, I would suggest as the outcome of such a set of instances the two provisional classes of acute circumscribed œdema:

a. Inflammatory—depending upon actual inflammatory processes in the papillary layer of the skin.

b. Neurotic—depending rather upon an angiomatous condition of the lymph-vessels of the corium due to alteration in nervous supply. To this latter variety might be applied, for the purpose of clearer definition, the term acute neurotic lymphangioma.

In the actual matter of treatment, too, there may a clearer line of separation be drawn between these two classes, the former depending largely for its alleviation upon local measures, the latter demanding general medication directed toward the removal of the systemic fault which is almost certainly present.

HOSPITAL NOTES.

INFIRMARY FOR NERVOUS DISEASES, PHILADELPHIA.

TREATMENT OF ATAXIA BY SUSPENSION.

The method of Motchonkowsky, of Odessa, introduced in 1883 for the treatment of tabes, and recently revived by Charcot, has been actively carried out in this institution for the past five weeks. In all, fourteen cases are under treatment. The method employed is practically identical with that recommended by Charcot, and consists in the suspension of the patient by the head and armpits for from two to three minutes. The Sayre apparatus can be used, or, what is equally convenient, the suspension made by means of pulleys arranged over a horizontal iron bar.

As a rule, the suspension is well borne. Care must be taken to have the pressure equable; not more in the neck than in the armpits. The slings beneath the arms need to be well padded and pushed well in; otherwise the pressure on the brachial plexus is unpleasant, and causes numbness.

Patients, after the suspension is over, are not released for a minute or so, as it is found that they are unsteady at first when let down.

The only unpleasant effect was in a patient who fainted during suspension and had convulsive movements; he recovered in a few minutes after being let down.

It is too early to speak as yet of the results obtained. There has not yet been in any case striking improvement.

MEDICAL PROGRESS.

The Treatment of Locomotor Ataxia by Suspension.—Prof. Charcot gives the following technical details, suggested by an experience acquired in the course of over 800 suspensions, practised under the supervision of his chief assistant, in the cases of forty patients. For, though the operation is in itself very simple indeed, it yet requires a certain skill that is more easily acquired with the assistance of definite rules, than by the sole experience of entirely original experiments.

The apparatus used is that contrived by Sayre, of New York, for the application of plaster jackets used in cases of spinal deviation. Though pretty extensively known, we shall give a short description of the form of it used in Professor Charcot's *clinique*. A transverse piece of iron, about eighteen inches in length, is suspended by means of a central ring to the pulleys which are used to lift the patient from the ground. Each extremity of the bar ends in a hook, intended to support the ring, which carries the straps intended to give support under the armpits. Several notches on the upper aspect of the bar serve to fix the rings from which hangs the head-piece. The latter consists mainly of two broad strips of leather, elongated oval in shape, moulded to receive the chin and the occiput respectively. These are connected above with the rings just mentioned, and are held in position by means of a strap sewn to the posterior flap, and fixed to buckles carried by the chin-piece, so as to hold the head-support in place when the patient is suspended. (Fig. 1.)

Much depends upon this strap, which must be tightened enough to prevent any slipping, and yet not sufficiently to cause compression of the bloodvessels of the neck, and thereby unpleasant head symptoms. It must be provided with a sufficient number of holes to accommodate itself to the varying thickness of the neck among those to be suspended. In case of need, which is not often, a soft body, such as lint or cotton-wool, may be inserted so as to prevent undue pressure of the strap or broad pieces upon the skin. It is necessary to exercise much care in fitting the head-piece and padding, so as to suit the peculiarities of each subject. The size of the head determines the notches into which the rings of the

head-piece are to be fixed; the larger the head the wider apart they must be, of course.

FIG. 1.

When the head is duly disposed of, the shoulder-pieces are slipped under the armpits. Though they may appear of minor importance, they really play the part of regulators during the period of suspension. For it is necessary that whilst lifted off the ground the patient should not be entirely supported by the head-piece, for then the traction would become, in some cases at least, absolutely intolerable. But though the weight of the body must be distributed upon other points, this additional support must not be so effectual as to prevent as complete an extension of the spinal column as possible.

FIG. 2.

The shoulder-pieces consist of elongated cylindrical padded cushions, terminating in straps provided with a series of holes so as to suit, by appropriate lengthening or shortening, the requirements of each patient. (Fig. 2.) This adaptation is very important; for if too short, the shoulder-pieces exercise such a pressure upon the axillary vessels and nerves as to compel the operator to bring the suspension to an abrupt and premature termination. If, on the other hand, they are too long, the traction on the structures of the neck may become too painful to be tolerated, and interfere likewise with the treatment.

Careful trials are necessary to determine the exact length of the several straps; but after three or four operations it becomes easy to decide the arrangement suitable for each case.

When all is ready, the physician orders his assistant—with some practice he may do without one—to apply traction upon the cord, very gently and slowly, so as to avoid jerks, and to accustom gradually the muscles and ligaments to the unusual tension to which they are going to be submitted. The patient is to be cautioned not to make any movements whatever whilst he feels himself being lifted off the ground, for they would give rise to unpleasant lateral and rotatory displacements. (Fig. 3.)

FIG. 3.

As soon as the toes cease to touch the floor, the operator holds the patient lightly, so as to check any oscillation or torsion of the cords, and carefully watches the number of seconds that elapse, so as to regulate minutely the length of each suspension. During this period the patient is made, at intervals of fifteen or twenty seconds, to raise his arms laterally away from the body, so as to transfer more weight upon the head-piece, and so render the traction upon, and elongation of, the vertebral column still

more complete, as complete as is tolerated by each individual. Much care and vigilance are to be bestowed upon the proper performance of these abductions of the arms, both by patient and physician. As a rule, the longest time of suspension must not go beyond four minutes, three minutes being taken as the average duration. Half a minute is enough at the outset, the maximum being gradually reached during the first six or eight applications of the treatment.

Here again it is essential to take into account certain individual susceptibilities or physical peculiarities, among which stands foremost the body-weight of the patient; for whilst a person weighing from about 130 to 150 pounds may be suspended forthwith during two minutes or more, the case is quite different in the case of those whose weight reaches 180 pounds or more. In the latter, the tension to which the structures of the neck are subjected may become very severe and painful, and be felt sometimes for a whole day afterward—an occurrence which must be avoided if the treatment is to be correctly carried out.

It is well to note that certain patients have such a wish—a very natural wish—to get better, that they think themselves bound to stand any amount of pain without complaining; but this circumstance is positively detrimental to the success of the treatment, which must be accompanied with but trifling discomfort at the most, without real pain or fatigue, lest it should defeat its own ends.

The maximum length of the suspension must, therefore, be suited to the requirements of each patient; it is obvious that in the case of heavy persons the effect on the spine must be very thorough and effective, owing to the greater traction to which it is subjected. Suspension must not be carried out oftener than once on alternate days, otherwise it may become more hurtful than beneficial. The time of the day is indifferent, but regularity in the operations is to be observed.

When the full time has elapsed, the operator very gradually lets the rope loose, so as to avoid every trace of jerking during the descent. The patient is to be supported whilst being freed from the apparatus, and made to rest awhile in an armchair brought near for the purpose.

The patient, before the operation, should divest himself from his coat, so as to give freedom to the arms, and his neck must be free from any pressure from the collar, so as to avoid any trouble or discomfort from compression about the neck. Sayre's original apparatus usually comprises a movable tripod, to the top of which the upper pulleys are fastened by means of a hook. This tripod is not to be used for suspending ataxics, who, being often deficient in power to sustain their equilibrium, are apt to seize convulsively its legs in order to steady themselves, and in so doing would knock down the whole apparatus, and injure themselves and the bystanders. As shown in the figure, the suspensory apparatus must be fixed to an iron ring firmly screwed in the ceiling.

The results obtained by Professors Eulenberg and Mendel at the Berlin Clinic for Nervous Disease in the cases of twenty ataxics, fully confirm, so far as can be judged from the comparatively recent introduction of the new treatment, the encouraging outlook sketched out in Professor Charcot's communications. The improvement observed bears chiefly upon the walking power, the equilibration, the lightning pains, and, in a few cases, the bladder troubles. Moreover, no bad symptom whatever has been observed, even in the case of the female patients who are undergoing the regular course of suspensions. At the same time, the most sanguine observer must acknowledge that it is entirely premature to come to any definite conclusions upon a point of such deep perplexity as the question of the possibility of absolute cure of locomotor ataxia. Physicians and patients alike must beware from falling into the temptation of conceiving exaggerated hopes as to the final results, in the presence even of effects as incontrovertible as those testified by so many able and critical observers.—*British Med. Journal*, March 9, 1889.

Acetic Acid in Gynecology.—The *Gazette de Gynécologie* states that solutions of acetic acid are as antiseptic as solutions of carbolic acid; the solutions are inoffensive, never producing any phenomena of poisoning, and are besides somewhat hæmostatic. Apart from this, acetic acid possesses the property of impregnating the tissues with a greater facility than other antiseptics; it has thus an advantage over sublimate, which latter, in the presence of albumin, produces insoluble compounds. Acetic acid injures instruments to a less degree than does sublimate; a pair of forceps can with safety remain fifteen minutes in a three per cent. acetic acid solution without being damaged. As soap is insoluble in acetic acid, one would have to wash his hands several times after handling the acid, an operation which is somewhat annoying. For ordinary antiseptic washings a three per cent. solution will suffice, while for cases of septicæmia a five per cent. solution is required.—*Revue de Thérapeutique*, March 1, 1889.

Treatment of Carbuncle by Iodoform.—Mr. Whitehead, of Manchester, has successfully treated three cases of carbuncle, by the subcutaneous injection into the base of the tumor of a concentrated ethereal solution of iodoform. In each instance a momentary burning pain was experienced by the patient, but this was immediately followed by permanent relief from suffering. On the second day the induration and redness had subsided, and the central slough was dry and withered. Within a week all traces of the disease had disappeared, with the exception of a dry superficial dark scaly scab, which eventually separated without leaving any conspicuous indication where the carbuncle had been.—*British Med. Journal*, March 2, 1889.

Chorea and Antipyrin.—Dr. Jules Simon states in the *Revue de Thérapeutique*, March 1, 1889, that antipyrin is the drug which has given him the best results in the treatment of chorea. He begins with the administration of eight grains, which quantity is increased every twenty-four hours by eight grains until he reaches the daily dose of sixty grains; this quantity suffices for children between the ages of fourteen and fifteen years. The mode of treatment is well borne, the author having only occasionally seen such symptoms as swelling of the face, scarlatinoid eruption or general fatigue follow the administration of the drug. But even these few annoying symptoms can be avoided if the drug be given in eight grain doses and at divided intervals during the twenty-four hours. The taking of some liquid after each dose will prevent gastric disturbances.

Aneurism and Epilepsy.—At the recent meeting of the local branch of the British Medical Association, one of

the most interesting demonstrations was that by Dr. Macewen. He showed, first, a man who had been subject to epileptic seizures for many years. A year ago Dr. Macewen removed a tumor from the cerebrum, with the result that the seizures have entirely ceased. The second subject demonstrated was a new method for the cure of aneurism, in which the object of the surgeon is to produce in the cavity, not blood-clot, but a "white thrombus" of connective tissue. This is accomplished by passing needles into the aneurism in such a way as to pass through one wall of the sac and just to touch the lining of the opposite wall; the current of blood causes an oscillation of the needle and a number of fine scratches on the inner surface of the endothelium, irritating it slightly and leading to the proliferation of leucocytes. From these connective tissue is formed, and a white fibrous mass develops on the inner surface of the sac. The irritation is repeated at interval of days, the needle being introduced at different spots. The result is the formation of a strong layer of connective tissue, which is firmer than red clot, and involves no danger from embolism.—*Lancet*, March 2, 1889.

Chloroform in the Treatment of Dyspepsia.—Chloroform administered in the various forms of dyspepsia overcomes fermentation and flatulence; it is best given in the following formulas:

1. *Method of* DR. WILS.—From ten to twenty drops of chloroform, to be taken in a few spoonfuls of sweetened water, in flatulent dyspepsia. After a few minutes eructations occur, followed by improvement.

2. *Method of* DR. HUCHARD.—Administer before each meal one dessertspoonful of the following:

℞.—Chloroform water . . . 150 parts.
Mint water . . . . 30 "
Water . . . . . 120 " —M.

Or, from eight to ten drops of the following mixture in a wineglass of water:

℞.—Tincture of nuc. vomica, Tincture of gentian, Tincture of anise } āā ʒj.
Chloroform . . . . gtt. xx–xl.—M.

An appropriate diet and oxygenated waters at mealtimes form part of this treatment.

3. *Methods of* DRS. REGNAULT *and* LASÈQUE.—This treatment applies particularly to painful dyspepsias with dilatation of the stomach:

℞.—Chloroform water . . . 150 parts.
Orange-flower water . . 50 "
Water . . . . . 100 " —M.

One dessertspoonful to be taken, at intervals of fifteen minutes, until the pain ceases.

Or the following for the same affections:

℞.—Chloroform water . . . 150 parts.
Tincture of anise . . . 5 "
Water . . . . . 145 " —M.

—*Revue gén. de Clin. et de Thérap.*, February 28, 1889.

Resection of a Portion of the Ileum.—DR. FREDRICO RUBIA, of Madrid, recently communicated to the Spanish Royal Academy of Medicine an interesting case in which he performed successfully a somewhat extensive resection of the gut in the wards of the Instituto de Terapéutica Operatoria of Madrid. The patient was a woman of thirty-two years of age, who, after eating a quantity of cooked vegetables, was seized with violent abdominal pain, a swelling appearing at the same time in the right groin. Vomiting and constipation followed. Subsequently the tumor in the groin became inflamed and opened in two places, viz., at the external inguinal ring and at the lower part of the right labium. From these fistulous openings feces kept continually escaping, rendering the patient's condition most deplorable. Attempts were made during many months to get these openings to close up, but, although temporary improvement followed some of the means used, it ultimately became evident that unless some radical operation was resorted to the patient must necessarily succumb. Having given purgatives and enemata to empty the bowels, and a disinfecting bath to cleanse the surface, Dr. Rubia performed laparotomy, making a small incision in the spot usually selected for the ligature of the external iliac. This brought into view the cæcum with the vermiform appendix. He then hooked up the coils of the ileum one after another; the third of these presented an opening with fungiform edges, three centimetres and a half in length by two centimetres and a half in breadth, and surrounded by a very unhealthy-looking area—which, indeed, occupied the whole circumference of the gut. Under these circumstances, it was felt that any attempt to close the opening would assuredly end in failure, and that the only alternative was to excise a portion of the gut. About eight centimetres were consequently excised, together with a V-shaped piece of the mesentery; catgut sutures were applied, and the patient made a good recovery, normal defecation taking place on the second day after the operation.—*Lancet*, March 2, 1889.

Permanganate of Potassium in Amenorrhœa and Dysmenorrhœa.—DR. J. M. LWOW (*Medicynsk. oboscenje*, 1888, No. 19. *Wratch*, No. 6) divides his 187 cases affected with these disorders into five groups: 1. Young girls, somewhat chlorotic, but otherwise healthy, who complain of severe pain during menstruation and of diminution of the amount of the flow, 32 cases. All were rapidly cured by taking from four to six grains of permanganate of potassium in extract of pulsatilla shortly before the period of menstruation. 2. Women suffering from extreme involution of the uterus after birth, or from atrophy of the uterus and ovaries, 17 cases. (With most of these patients two years had passed since they last borne children.) Permanganate of potassium taken in the same doses from three to six months without interruption, reëstablished already, in four or six weeks, the menstrual functions, which remained regular provided the drug was continued. 3. Slow involution of the puerperal uterus in connection with old, inflammatory processes of the uterus and its appendages, with slight but very painful menstruation, 62 cases. Here the results were also satisfactory, although some cases proved unsuccessful—namely, those in which puerperal illness had left irreparable changes. 4. Blennorrhœa of the vagina and uterus, 65 cases. In these cases the drug, though continued for some time, had no effect whatever. 5. Women in whom menstruation had begun too early and ceased between the ages of thirty-five and forty, 11 cases. No results.—*Therapeutische Monatshefte*, February, 1889.

The Medical News.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES . . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,

PHILADELPHIA.

SATURDAY, MARCH 23, 1889.

RECENT ADVANCES IN THE DIAGNOSIS AND TREATMENT OF DISEASES OF THE STOMACH.

The process of taking stock, of finding out the exact amount and nature of our possessions, is at least as valuable in the mental as in the physical world. In a paper read before the Medical Society of Munich, on December 4, 1888, Stintzing has done this important work for the department of diseases of the stomach. After a critical examination of the various methods of testing the functional capacities of this viscus, he propounds the only question of interest to practical physicians: What have they taught us? In the first place, as he tells us, we have learned the paramount importance of hydrochloric acid in the act of digestion. It is not so long since pepsin was regarded as the panacea of every gastric trouble, whereas we are now well aware that in the gradual disappearance of the digestive agents pepsin never takes precedence of hydrochloric acid. We have learned to recognize the two extremes of anacidity and hyperacidity, and for a time were inclined, in accordance with the researches of von den Velden and Riegel, to regard the former as pathognomonic of carcinoma. Although we are now aware that hydrochloric acid may be absent in other morbid conditions, such as dilatation without carcinoma, motor insufficiency, chronic catarrh, and atrophy of the mucous membrane, yet its absence in carcinoma is a diagnostic point of the greatest importance. For example, the differential diagnosis between simple ulcer and carcinoma is now rendered a comparatively easy matter, since hydrochloric acid is never absent in the former disease. On the other hand, Stintzing declares that he has never found it in carcinoma, but does not state in how many cases of this disease he has tested the gastric secretions.

The symptom called pyrosis has long been recognized as due to hyperacidity, although the nature of the acid or acids causing it was, until recently, unknown. It is now established that there are two varieties of pyrosis, one depending upon an excessive secretion of hydrochloric acid, the other upon organic acids caused by abnormal fermentations. For the former, Sticker has proposed the term *pyrosis hydrochlorica*. Hyperacidity is a frequent though not an invariable accompaniment of gastric ulcer.

The new methods of research have enabled us to distinguish from hyperacidity a condition of hypersecretion, by which is meant the secretion of gastric juice by a fasting stomach. This condition is by no means fanciful, but is a well-recognized and serious pathological aberration. According to Riegel, there may be withdrawn from a hypersecreting stomach during a fasting interval as much as a pint of acid fluid capable of digesting albumen. The causes of this condition, which was discussed in The Medical News, October 1, 1887, are not fully known, although it is probable that they often have their origin in the nervous system. In support of this view, it may be mentioned that Sahli has observed a hypersecretion of gastric juice during the gastric crises of a tabetic patient. The condition of hypersecretion may, therefore, be either transient or permanent, and in the latter event is generally associated with dilatation. In the first thirty to forty-five minutes of digestion the acidity of the gastric juice is caused by lactic acid. If this acid appears in later stages of the process, its presence is caused by undue detention of food or by deficiency of hydrochloric acid. The tests for lactic acid are, therefore, of importance in the diagnosis of diseases of the stomach.

Studies of the milk-curdling ferment, the *labferment* of the Germans, have lately been instituted by Johnson, Klemperer, and Boas, and the latter has shown that as pepsin is preceded by propepsin, so is the labferment by labzymogen. The latter is developed into the former, and acquires its milk-curdling property by the action of hydrochloric acid. Labferment is always present in the stomach, except in high degrees of atrophy, and even in these its forerunner, labzymogen, may be found. The diagnostic value of the absence of this ferment is no greater

than that of hydrochloric acid, on the action of which, as already stated, it depends for its existence.

The absorbent power of the stomach may be tested with iodide of potassium, which was first employed for this diagnostic purpose by Penzoldt and Faber in 1882. Three grains of iodide of potassium are given in a gelatine capsule, and the saliva which has been previously shown to be free from iodine is tested for this substance. If the stomach is healthy and empty, the first iodine reaction appears in from six and one-half minutes to eleven minutes. If the capsule be swallowed immediately after a meal, the reaction does not appear until from twenty to thirty-seven minutes have elapsed. According to Stintzing, it may not appear, under these circumstances, until forty-five minutes after the capsule has been swallowed. In dilatation of the stomach, in cancer, ulcer, and chronic catarrh the absorbent power of the stomach has been shown by this test to be diminished.

The digestive and absorbent powers of the stomach having been tested, the examination is completed by ascertaining its motor ability. Until quite lately, the only means of determining this point was based upon the fact that a healthy stomach has discharged its contents into the intestine seven hours after a meal. It the stomach was proved to have emptied itself in that time, its motor function was assumed to be normal. Such a method, however, gave no reply to the question whether the gastric peristalsis had begun at the proper time. Quite recently a drug was discovered, or, rather, invented, the chemical properties of which rendered it singularly valuable as a test of the motor function of the stomach. This drug, which is salol, is insoluble in the acid secretions of the stomach, but dissolves in the alkaline fluids of the small intestine, in which it breaks up into its component parts, phenol and salicylic acid. The latter is excreted with the urine, in which it may be recognized by testing with chloride of iron. In health, according to Ewald, this reaction may be obtained in from thirty minutes to one hour after the ingestion of fifteen grains of salol; whereas, in cases of gastric dilatation the reaction, as a rule, does not appear until from ninety minutes to three hours after the same dose. These figures, of course, include the time occupied by the stomach in propelling the salol into the duodenum plus that necessary for the salol to be decomposed, absorbed by the portal vessels, pass the barrier of the liver, enter the general circulation, and be excreted by the kidneys. Ewald and Sievers, by experimenting in a case in which colotomy had been performed, determined this latter period to be between twenty and thirty minutes. By subtracting these sums from the average time in which the urine reaction is obtained, viz., forty-five minutes, it would appear that the time necessary for the healthy stomach to expel a dose of salol into the intestine is from fifteen to twenty-five minutes.

This salol test can scarcely be called clinical, for, apart from the delicate nature of the urine test, which is a part of it, it is impossible for most individuals to pass their urine at intervals sufficiently short for the object in view. On these accounts Stintzing has attempted to apply the test for iodine in the saliva to the determination of the motor function of the stomach. He administered iodide of potassium in keratin pills—which are, theoretically, insoluble in the stomach—and tested the saliva, at intervals, for iodine, just as is done in testing the absorbent function. At the first experiment, the iodine reaction appeared in exactly the same time as the salicylic acid reaction in the urine after the ingestion of salol. Stintzing, however, conceived the happy idea of examining the stomach contents for iodine, and found it present. It might have been swallowed, and, therefore, in a second experiment, as soon as the first traces of iodine appeared in the saliva he withdrew the stomach contents and found the iodine reaction to be much stronger in them than in the saliva. The method is, therefore, inapplicable to the object in view, and the experiment demonstrates that, as already suspected, keratin pills are not insoluble in the stomach.

The latest test of the motor power of the stomach is that just presented by Klemperer. This experimenter introduces into the empty stomach 26 drachms of olive oil, and after a certain time washes out what is left in the viscus. The deficit determines the motor capacity. Under normal circumstances, the stomach discharges from 18 to 21 drachms of the ingested oil into the duodenum in two hours. In cases of chronic catarrh only from 6 to 11 drachms out of the 26 were emptied in the same time, and in a case of atrophy only 6½ drachms. Supposing it possible to wash out all the ingested oil, Klemperer's test is the most accurate yet employed, but the question arises whether the behavior of the stomach toward a quantity of oil so great as virtually to constitute a foreign body, is the same as toward the ordinary nutritious substances.

The difficulties in the way of the general clinical use of this test are also, it is needless to say, insuperable.

The most important results of modern gastrological research have now been enumerated, and it must be admitted that the array of precise therapeutic indications which they furnish is unequalled in any other department of medicine. Nearly forty years ago one of the greatest clinicians of Germany gave utterance to almost hopeless views concerning future progress in the knowledge of diseases of digestion. Through the methods above outlined, and especially through the use of the sound, this pessimism of Frerichs has been shown to be without real foundation.

ACCIDENTAL DEATHS AMONG INFANTS.

Infant mortality by accident and negligence is a marked figure in English statistics, especially in regard to the deaths of male infants. The annual summary of the Registrar-General for the year 1887 makes it clear that not only neglect in regard to infant life prevails, but that there is a ruthless sacrifice of it worthy of the days of Herod. In London more than half of all accidental deaths among males falls upon children under five years; among females, over three-tenths. For all England, one-fourth of all deaths by accident among males falls upon those under five, and among females about the same proportion. But totals being next considered, there are nearly twice as many males as females registered as dying in this class, thus: males, all ages, 11,103 deaths; females, 4415; total, both sexes, 15,518. Under five, males, 2150; females, 1712; total accidental infant mortality being 3862.

The excessive loss of infant males in London and some other large cities has been studied and theorized upon not a little, but a satisfactory explanation of its causation has not yet been found. In it is one of those unsolved problems that stand up to challenge the efforts of the humane and philanthropic for the reduction of violent causes and for an increased watchfulness and care for infant life.

At their recent annual commencements, the degree of Doctor of Medicine was conferred by the respective institutions as follows: University of Louisville, 129; Medical College of Ohio, Cincinnati, 85; Long Island College Hospital, 47; Woman's Hospital Medical College, Philadelphia, 36; Miami Medical College, Cincinnati, 22; Baltimore Medical College, 21; Michigan College of Medicine and Surgery, 11.

The collections in New York City for the Hospital Saturday and Sunday Fund amount to $51,250, a slight increase over the total for last year, when $50,500 were received.

At the dinner of the Alumni of the Long Island College Hospital, on March 13th, an agreeable surprise interrupted the feast, in the shape of the presentation of a check for $10,000 in aid of the work of the Hoagland Laboratory. The donor, the venerable Dr. Daniel Ayres, has been all his life long a diligent pathologist, and has reason to know the advantages of a fully equipped laboratory.

The University of Vermont has given expression to the growing appreciation of the medical relations of life insurance by the origination, in its medical department, of a new chair having for its title the Professorship of Physical Examination for Life Insurance. The Faculty have selected Dr. Charles F. Stillman, of New York City, as the first occupant of this chair.

The number of Americans taking the clinics and special courses at Vienna, according to the *Gazette Médicale de Paris*, appears to increase with each succeeding year. The practical courses given by the "Privat-docents" are the most popular. The Americans are credited with paying liberally, and are welcomed with *empressement* by the professors of the various specialties.

REVIEWS.

A Treatise on the Diseases of Women, for the Use of Students and Practitioners. By Alexander J. C. Skene, M.D., Professor of Gynecology in the Long Island College Hospital, etc. 8vo. New York: D. Appleton & Co., 1888.

This is a practitioner's text-book, for the use of practitioners. Dr. Skene has made no attempt to compile an encyclopædia, nor to state the theories regarding the functions and diseases of women; he has thought out for himself the problems which confront the practitioner of gynecology and embodies his conclusions in clear and forcible language. The work is especially well illustrated; after the discussion of each subject are placed clinical histories of cases explaining the previous text; the pictorial illustrations are the best we have seen upon this subject.

After a succinct account of methods and instruments for examination the facts known regarding menstruation are briefly stated; disorders of menstruation are treated

of by the narration of illustrative cases without theoretical discussion, an uncommon, but admirable method. Flexions of the uterus, often so little amenable to treatment, the author manages with fair success by amputating or resecting the cervix, correcting the imperfect invagination of the cervix by a plastic operation, or the stem pessary, as the case demands; he regards dilatation of the cervix to permit the introduction of the index finger dangerous and unnecessary,

Injuries to the pelvic floor are treated with great clearness and thoroughness. The difference between properly and improperly applied stitches; the fallacy of closing a skin laceration to the neglect of deeper structures; the importance of injury, relaxation, and paralysis of the deeper structures of the pelvic floor are all impressed upon the reader's mind and well illustrated; this is one of the most satisfactory sections of the work.

Sclerosis of the uterus, the result of areolar hyperplasia, receives especial description from Dr. Skene, by whom the descriptive term was introduced. Membranous dysmenorrhœa the author believes to be caused by deranged innervation, malnutrition, and ovarian excitation, and not by inflammation; his belief is founded on clinical experience.

Lacerations of the cervix are treated with the richness of illustration which is remarkable in the section on lacerations of the pelvic floor.

For displacements the author prefers the surgical term dislocations of the uterus. In discussing the mechanical support of the dislocated organ the views of Dr. Frank P. Foster are adopted; a section illustrating the abuse of pessaries warns against this blunder, while their judicious employment is commended and clearly illustrated. Alexander's operation has not been found a necessary expedient by the author. The electrical treatment of fibromata, as employed by Engelmann, is described; Keith's operative procedures in grave cases are narrated, and some very interesting cases illustrating the natural history and spontaneous cure of fibromata are recorded.

The author believes that "a great many affections of the brain and nervous system are due to disease of the ovaries." He applies the term "tubo-ovariotomy" to the operation often called "the removal of the uterine appendages"—a term he considers absurd. The diagnosis and operation for ovarian tumors are very clearly described; the author is not infected with the modern fear of morphia for pain after ovariotomy, and in his hands flatulence is relieved by quinine *per rectum*, and not by salines. The author's mental focus regarding affections of the Fallopian tubes is apparently normal, for they receive treatment proportionate to their frequency and importance at his hands. Diseases of the pelvic peritoneum and cellular tissue and of the bladder and urethra are treated with the same practical facility which characterizes other portions of the work.

From extensive investigations in Kings County Asylum, Dr. Skene has prepared an extremely valuable paper on "Gynecology in its Relations to Insanity in Women." While disease of the female reproductive organs not infrequently causes insanity the local disease in many cases is a symptom of the general implication of the cerebro-spinal centres of the organism in processes whose most marked manifestations are in a disordered mind. Hence there are cases in which the gynecologist can aid greatly in restoring the balance of mind and body by removing local irritation, while there are other cases in which his efforts must be confined to diagnosis only.

This chapter closes appropriately one of the most practical works on gynecology in the language. In his desire to concentrate the reader's attention on the fact under discussion Dr. Skene omits all references and statements of theory only; what the writer has proved by personal labor and observation, admirably illustrated by words and drawings, is clearly and tersely given. We know of no more reliable source of practical information on gynecology than this book.

J. LEWIS SMITH, M.D., IN THE CHAIR.

TUBERCULOSIS OF THE TESTICLE IN AN INFANT.

DR. KOPLIK presented a child two years of age, whose father had died of chronic pulmonary disease at the age of thirty-six. The child had coughed since birth, and eight months ago the left testicle began to swell. At present the testicle is the size of a hen's egg, not painful to the touch; the scrotum showed a fistulous opening leading into the diseased organ; the pus from this fistulous tract contained tubercle bacilli. Another fistula was situated in the calf of the leg. The child suffered from occasional diarrhœa. There was an area of dulness in the lung, and numerous glandular swellings all over the body.

DR. A. JACOBI remarked that tuberculosis of the testicle is rare in the young. In the case presented, the many swollen glands indicated general tuberculosis. He thought local treatment out of question, and believed general treatment to be of little benefit. The fistula in the calf of the leg appeared to come from the fibula.

DR. CARR stated that Monks had reported a case of tuberculous testicle in a child five months old, in the *British Medical Journal*, December 27, 1884.

DR. J. H. HOLGATE showed a child, three years old, illustrating

REFLEX MOTOR DISTURBANCE,

from accumulated smegma underneath an adherent prepuce. The child had been unable to walk at the age of two and a half, its limbs being flexed at the hip and knee, and it suffered from dysuria. After proper treatment of the prepuce, these symptoms disappeared, and the child could now walk alone. He also showed a child one and a half years old, whose persistent enuresis had stopped after freeing the glans penis from an adherent prepuce.

DR. T. HUBER presented two children upon whom he had operated for

PERITYPHLITIC ABSCESS.

In the one case (a boy of ten) the prominent symptoms were pain in the ileo-cæcal region, vomiting, and diarrhœa. In consequence of beginning peritonitis with tympanites, the usual dulness and tumor were absent.

The aspirating-needle revealed pus, which was evacuated by a free incision followed by drainage. On the third day the dressing showed fecal matter. Recovery was complete after two weeks. In the second case the inflammatory tumor was located in the right iliac fossa. The abscess was cut down upon and evacuated. Four days later a large piece of sloughed tissue passed away, and a fecal concretion was found on the dressing on the twenty-third day. Recovery took place in due time. In his experience over a dozen cases of perityphlitis had terminated in resolution.

During childhood the appendix vermiformis is, as a rule, very long. Most cases of perityphlitis occur in males, previous peritonitis being a predisposing factor. A prodromal stage of several weeks is not unusual, a tingling in the right leg being one of the symptoms. Occasionally it may be difficult to differentiate beween hip-joint disease, acute oöphoritis from gonorrhœal infection in young girls, and perityphlitis. But an examination per rectum will often suffice to locate the trouble. Aspirating-needles should be inserted obliquely. Gill Wylie advocates laparotomy in the median line in doubtful cases.

Prognosis in the young should be guarded. As regards treatment we should order rest, liquid food, opium, morphine hypodermatically, and not purgatives. According to Lawson Tait, salines are indicated after operation. As a topical measure, the ice-bag or hot turpentine stupes should be employed, and the rectal tube to remove flatus. As regards operation, Dr. Bull advises, the more rapid the symptoms, the sooner surgical interference.

Dr. Hanks remarked that, as far as his observations went, cold had some influence in promoting suppuration, which, when once established, should have prompt surgical treatment. The differential diagnosis between perityphlitis, intestinal obstruction, and disease of the tubes in girls might be difficult.

Dr. Jacobi said that the laxative treatment in perityphlitis was, in his opinion, superior to opium treatment; the presence of a laxative in the intestine would assuredly do less harm than the presence of fecal matter. He remarked that authorities differ totally with regard to the treatment in perityphlitis. He remembered one case in which life was saved by not interfering in a period of collapse, and operating two weeks later. Perityphlitis is seldom primary; children may have many attacks and recover. It is impossible to make rules for all cases, and it is safe to wait a reasonable time before operating. Subacute and chronic peritonitis are common, and should receive attention in practice.

Dr. Wendt spoke of injudicious interference in perityphlitis, and of the difficulty of formulating general rules for surgical treatment.

Dr. Wiener said that nine cases had come under his observation; of the six operated upon, five were children. An operation was indicated by a sudden increase in symptoms. He preferred the opium treatment, gave enemata, and incised if he found pus.

Dr. O'Dwyer read a paper on

PULMONARY ATELECTASIS.

In fatal cases of croup he had always found atelectasis associated with inflammatory infiltration of the alveoli. Collapse begins when inspiratory power is diminished from mechanical obstruction or feeble inspiratory muscles. The air pressure within the lung plus normal adhesion of pleural surfaces is greater than external atmospheric pressure. When a renewal of air is prevented, the residual air is absorbed. Every atelectatic lung is also a congested lung. As regards treatment of atelectasis in infants, he had found the momentary closure of the mouth and nose of service, and had devised an instrument for direct inflation through the larynx, the instrument acting as a catheter and larynx tampon at the same time. In conclusion, Dr. O'Dwyer requested a discussion on two points, viz: 1. Is atelectasis, uncomplicated with inflammatory changes in the alveoli, ever found in fatal cases of croup? 2. By what force is a collapsed lung inflated when freely exposed to the atmospheric pressure through an opening in the pleural cavity (*e.g.*, empyema)?

Dr. Northrup opened the discussion by stating that classical atelectasis does not admit of an inflammatory definition. He had examined many lungs microscopically, and had never found a pure atelectasis in descending croup. Usually there was distinct evidence of capillary bronchitis and broncho-pneumonia, probably caused by insufflation.

Dr. E. C. Wendt stated that in the cases under consideration he had always found inflammatory changes in the collapsed lung tissue, and that inflammation followed atelectasis. Moreover, a collapsed lung does not always expand, and if it did in the presence of an opening in the thorax, such an inflation might be favored by a valve-like opening which would interfere with free atmospheric pressure.

Dr. H. Jacobi remarked that lobular atelectasis was the first stage in pulmonary collapse. Rarefaction of air and a viscid, mucous catarrh being frequent causes of atelectasis, innervation might also be lost. He was not prepared at the moment to give a definite answer to the second question.

Dr. Carr suggested that expansion of a collapsed lung was probably favored by inflammatory adhesions.

Dr. Caillé remarked that we have two forms, the obstruction and the compression atelectasis. In the former inflammatory changes are found in the alveoli as a rule, and, according to recent research, the act of coughing may force bronchial secretion into the finer air-passages, and finally into the alveoli. In compression atelectasis inflammatory changes are not found, if the compressing liquid be removed in good time. When this is neglected we frequently observe that a collapsed lung does not inflate after late removal of the compressing cause. With regard to the force necessary to inflate a collapsed lung, he would state that in a case of double empyema following typhoid fever, which had recently come under his observation, he had incised and drained the thorax on both sides. The external atmosphere had free access to both sides of the thorax, but probably owing to adhesions the external pressure on a limited surface was not sufficient to overcome natural inspiratory action; thus the collapsed portions of the lung became inflated, and the patient—who finally made a complete recovery—could, by placing a whistle in his mouth, produce a whistling sound by inspiratory effort.

Dr. O'Dwyer closed the discussion by stating that with regard to the second question he could not accept the explanations which had been offered. In his opinion, the affinity of the hæmoglobin of the blood for oxygen

in a congested and collapsed lung was the true inflating power.

Stated Meeting, February 15, 1889.

A. B. JUDSON, M.D., CHAIRMAN.

DR. LEWIS H. SAYRE presented a case which was of interest on account of

DISEASE OF THE HIP AND KNEE IN THE SAME LIMB.

The boy, aged six years, three years ago had scarlet fever, which resulted in an otorrhœa. Some time afterward he was noticed to have disease of the right hip-joint, which was treated by rest in bed for two or three months, and afterward by traction apparatus. According to his parents, he apparently recovered in about nine months, with almost perfect motion. The instrument was then removed, and he was allowed to run about. The disease was redeveloped in the hip, and during this time he had acute synovitis in both knee-joints, which was treated by rest and plaster-of-Paris. The left knee has entirely recovered. When first seen, two months ago, the right knee was flexed to 140°, subluxated, and presented the usual deformity of chronic knee-joint disease, with excessive tenderness over the internal and external coronary ligaments. The right thigh was flexed on the pelvis and abducted, there was considerable muscular spasm, and he presented all the evidences of disease of the hip-joint, with the second stage pretty well advanced. He was treated first by rest in bed, with extension made in three directions, viz.: (1) on the thigh in the line of the deformity of the hip; (2) in the axis of the leg; and (3) just below the head of the tibia, to draw it forward and decrease the angle. Now the flexion at the hip has almost disappeared, and that at the knee is much improved. The question arose, How to construct an apparatus which would allow the boy to get around, and make traction at the same time upon both the hip- and knee-joints? He had had an instrument constructed, consisting of his father's ordinary knee-extension splint, with an extension piece under the foot, and supplemented by a pelvic belt and a ratchet-bar like that used in the ordinary extension apparatus for the hip-joint. It is applied with plasters above and below, to fix the knee-joint, and extension is made on this joint by a ratchet, as in the ordinary hip-splint. So far, the case has done extremely well with this apparatus. He presented him partly as a curiosity, and partly to get suggestions for improving the mode of applying the apparatus.

DR. A. B. JUDSON was reminded of Dr. Hilton's apparatus mentioned in his book on *Rest and Pain*. He had amputated the knee, and the patient recovered rapidly from the hip disease. Hilton explains this by saying that the amputation above the knee enabled the muscles to keep at rest, or, as he puts it: "In fact, I may say, the hip-joint was cured by cutting off the leg."

DR. N. M. SHAFFER had a case with disease of the hip, knee, and ankle, all on the one side. He first put on a modification of Dr. Taylor's Dows' instrument, supplementing it with a lateral bar on the inside, and an adjustable knee-joint, so that the joint could be placed at any angle desired. The instrument was placed inside the shoe, and a traction rod below the knee. He finally put on an apparatus which made traction on the hip, knee, and ankle, at the same time. The patient entirely recovered. The advantage of having an adjustable knee-joint is, that one can place the instrument so as to correspond with the exact angle at the knee. With a traction rod above and below the knee, and adhesive plaster independently connected with each traction point, one can get very excellent results.

DR. A. M. PHELPS said that the apparatus seemed to fix the knee-joint to a certain extent, but he would suspect a little giving at the knee, or flexion at the hip, from the movement of walking. He had usually employed an instrument similar to the one used by Dr. L. A. Sayre in connection with a hip splint but not attached to it; when the patient stepped it allowed the knee to move up and down, but there would be no motion at the knee-joint. A later report on the case presented would be interesting, with reference to the question of relapse.

DR. H. L. TAYLOR read a paper on the

PREVENTION AND TREATMENT OF CRURAL ADDUCTION.

(See page 315.)

DR. GIBNEY asked whether the motion in the hip which was present when the case first presented itself, was progressive or not, because the statistics of Drs. Shaffer and Lovett showed that the amount of motion did not increase after the cure of hip-joint disease. Dr. Taylor's case seemed to have had considerable increase in the motion from the time when it was pronounced cured.

DR. TAYLOR replied that the patient was thirty-five years old now, and had had the disease since she was nine years of age, so that the early history of the case was necessarily rather obscure. She was twenty years old when she first came to the New York Orthopædic Dispensary, and when Dr. C. Fayette Taylor resigned she followed him, and continued under his treatment. She came to the dispensary in the condition mentioned, and all that he knew was that since then she has been well for several years, with an amount of motion which, so far as he could estimate, had remained practically unchanged.

DR. SHAFFER was especially interested in the study of the muscular relations of these conditions, to which attention had been called, and wished to speak especially on that point. He did not know why we have adduction when we suppose our cases to be cured. When Dr. Lovett and he were studying the cases they reported, he was struck by the fact that cases supposed to be cured, and who left the dispensary in pretty good condition, with a tolerably straight limb, without much adduction, after eight or ten years' release from active treatment, would show on examination not only an increased adduction, but also lessened mobility; and the question presented itself to them whether the cases really were cured when discharged. He has come to believe that adduction occurs only in cases where there is a condition of disease which has not been absolutely cured. These cases were, of course, dispensary patients, but they were discharged as cured only after being studied for perhaps two or three years. He pursues the same lines of treatment as Dr. Taylor has mentioned, when he can properly control the conditions of treatment, his apparatus being based on the same general principles; but he thinks the apparatus should represent more distinctly the element of traction than is done in the excellent instruments presented for

examination. The question he especially emphasizes, is that as a result of study and experience we discharge our cases when there is tolerably good motion, and perhaps only a very slight degree of adduction or of rotation, and the case is regarded as cured. Such cases ten years later show lessened mobility and increased adduction. The muscular expression in these cases is very important, and enables us to make our diagnosis in hip disease long before we have deformity; and so he felt that in the cure of hip disease we should regard the muscular signs and the tendency to adduction as showing that protective treatment has not been pursued long enough. He asked whether the sign of adduction, after a supposed cure, should be regarded as a sign that there is an irritation or some lingering disease which gives, so to speak, a reflex contraction of the muscles, corresponding to that observed in the earlier stages of the disease.

Dr. Phelps thought that Dr. Shaffer was correct in saying that the muscles indicate the condition of the joint. There is a condition in the joint or about it, usually in the bone, which causes the reflex spasm. Why do we treat the spasm alone? It is only a symptom of the disease within the joint. In the treatment of adduction we should aim to immobilize the joint, to control inflammatory action in the joint, to control intra-articular pressure; and when this is done, we will not have muscular spasm. Any splint which will increase the intra-articular pressure is a wrong splint, and many of them do this. The armamentarium presented is highly ingenious; but more than fifteen years ago Dr. Sayre taught us, if we put these cases in bed and apply the long splint to the well leg with extension to the diseased one we relieve spasm and overcome deformity. He believed that is entirely correct. At the Post-Graduate Hospital, where he has a number of cases now, he has treated them in this manner, and when the muscles fail to yield he does not hesitate to cut them, and overcome the deformity. He then puts the limb in proper position, so that when he makes extension the muscles are not used as a fulcrum and the limb as a lever, thereby producing intra-articular pressure, which he believes to be one element of destruction in hip-joint disease. Extension is made in a line corresponding to the axis of the neck. It is well in the case of children to put them in some fixative apparatus, such as the cuirass or portable bed; but, in any case, keep the joint absolutely immobilized. After this period has passed, by using a modification of the long traction splint we prevent crural adduction, flexion, and many of the abscesses which follow, and put our patients under the most favorable circumstances for cure. Intra-articular pressure is thus relieved, and Nature will take care of such a case if she can do it at all. These expensive instruments are not available among the poorer classes, neither do they fulfil all the requirements in the management of these deformities when disease is frequent.

Dr. Shaffer thought that Dr. Davis ought to have the credit for making the original statement that we should not use the muscles as a fulcrum so as to increase the pressure in the joint. In his book he says: "When the extension force is used, do not use the bone as a lever, prying over the fulcrum (contracted muscles), forcing the head of the bone up into the acetabulum." That was written in 1867, and, so far as he knew, was the first positive statement regarding the incorrect principle of applying traction in the wrong line, and showing the reasons why we should not do it. With all due deference to Dr. Sayre, it seemed to him that Dr. Davis ought not to be forgotten, for he believed he was the first one to bring it prominently before the profession.

Dr. Phelps objected to this on the ground that Dr. Davis did not tell us how to do it.

Dr. John Ridlon thought that the position taken by Dr. Phelps was one of considerable importance—that it should be our aim to prevent this deformity of adduction as well as to cure it when the cases from somebody else come to us with it. He was very glad that Dr. Taylor so frankly brought the matter forward, and stated that the *majority* of these cases treated by traction with portative apparatus do get well with flexion and adduction. When a patient comes to us with flexion or adduction, the particular method of treatment adopted will depend upon whether it is cured or not. If it be cured, and the adductor muscles are shortened and not in spasm, and the leg is shortened from shortened adductor muscles, and not from spasm, he saw no reason why those adductor muscles should be stretched rather than divided. If the case be not cured, and the adduction be due to muscular spasm, then we should treat the joint disease rather than try to relieve the adduction; and upon that comes up the question whether traction in any line is advantageous or is harmless in a case of hip disease with adduction.

It seemed to him that traction upon a leg in a patient whose adductor muscles are in spasm does produce some pressure at the point of the disease in the bone, whether intra-articular or extra-articular. He did not think, however, that we are perfeetly unanimous as to whether that pressure is harmful or not. If the adductor muscles are in spasm, let us go to work deliberately and rationally, and endeavor to treat the case just as we would if we saw the case for the first time in the earlier stages of hip disease. Just so long as any muscle or group of muscles is in spasm, and which, if left to itself, will produce deformity in any line, that joint, as a joint, should be kept in perfect rest; there should be absence of motion and absence of pressure, whether from superincumbent weight or muscular spasm; and if the deformity is due to muscular spasm, he had no question in his own mind that the deformity will be relieved so soon as the disease is cured.

Dr. Shaffer thought we were not justified, if we have reflex muscular contraction, in dividing muscles which would yield under ether, simply on the principle that we assume that it is reflex contraction. After being divided, the trouble recurs as soon as union has taken place; at least, he had seen such cases.

Dr. Phelps, in answer to a question from Dr. Shaffer, as to what was his rule in dividing muscles, said: Any muscle which can be stretched under ether, or which by extension for a short time will allow the deformity to be overcome, he should not think of dividing; but if, in a case of hip-joint disease of one or two years' duration, the tensor vaginæ femoris, the fascia lata, and the adductors were tense and would not yield to force under ether, he would cut these tissues. He could do it with perfect safety, and pull the limb down straight, and then put on proper retaining apparatus.

Dr. Judson said that the question, "What determines the direction of the limb in the deformity of hip disease?" was one of considerable interest. Why should one patient

present abduction and another adduction, and why does one patient have extreme, and another one moderate flexion?

It appeared to him probable that the limb, as a rule, assumes that position which the patient finds most habitually comfortable and convenient. If, for instance, the patient finds that with the limb in a certain position he is able to avoid inadvertent motions and accidental concussions, the limb will be found in that position. If he is in bed for a long time with a painful joint, the position will be extreme flexion and adduction, because the painful joint is thus made easy. The choice is not so much the result of deliberate experiment and deduction, as the result of instinctive and reflex action. If these views are correct, it ought not to require much force to reduce the deformity in the acute stage; and he had no doubt that it is common to see the deformity of the early stages taking different directions and degrees from time to time in a given patient. The simplest methods sometimes suffice to effect a change. For instance, the long hip splint, even if it had no other function, would be useful, because it combats extreme flexion of the thigh by keeping the knee straight, extreme flexion of the thigh being impossible unless the hamstrings are relaxed by flexion of the knee. He recalled the case of a patient in whom the traction of the hip splint, the patient being in bed, converted marked adduction into marked abduction, which in turn was reduced by the unconscious action of the patient when he began to walk, still wearing the hip splint. But this tractable condition of the joint is, of course, found only in the early or acute stage of the disease. In time, structural changes take place, and compel a resort to force. The correction of adduction caused by structurally shortened muscles and ligaments, is a very difficult but by no means impossible thing. The apparatus shown and explained for effecting this object by the use of the rack and pinion, with pressure applied to the os innominatum of the opposite side, appears to be nearly perfect as a mechanical device, and accomplishes the object intended.

DR. TAYLOR, in closing the discussion, said that the paper was on the subject of adduction, and not on the treatment of hip disease, which is a very much broader subject, and that the earlier forms of adduction from reflex muscular spasm required nothing more than the proper traction treatment. He gave two or three classes of cases in which the treatment of adduction would be different, according to the stage of the disease, and he especially emphasized—and that was the object of the paper—the treatment of adduction in old cases who had had hip disease and returned for treatment ten to thirty years after the deformity had occurred. In these cases there was structural shortening of the muscles, connective tissue, and ligaments, and in many of them there were very firm adhesions in the joint. The plan of treatment which he recommended is applicable especially to such cases, whether due to hip disease or any of the other conditions mentioned. He did not wish anybody to infer that one must have all this paraphernalia in order to get on in the earlier stages of the disease. He was quoted as saying that the majority of cases properly treated with traction, get well with adduction. What he did say was, that the majority of cases one sees on the street have been cured with adducted thighs. He was far from thinking that those patients were treated by what he would call properly applied traction. On the contrary, adduction can nearly always be avoided where one can get the co-operation of the patient, and after it has occurred, it is nearly always susceptible of cure by proper mechanical means, no matter how long after its occurrence the patient comes under treatment.

He was the last one to advocate symptomatic treatment in hip disease. Our whole plan of treatment is based on thorough and prolonged protection of the joint, and under this plan deformity and other severe complications are much less common than under less thorough methods.

CORRESPONDENCE.

AUTOMATIC AMBULATION.

To the Editor of THE MEDICAL NEWS,

SIR: During a visit to Paris, a few days since, I saw the following very extraordinary case brought into his clinic at the Salpêtrière by Charcot, and described by him to be a case of "l'automotisme ambulatoire."

The patient, a man of, perhaps, forty-five, had been for nineteen years a bookkeeper in a merchant's counting-house, and had always enjoyed the utmost trust and confidence of his employer, who retired a year ago from his business, which went into other hands, the old bookkeeper remaining, however, in his confidential position. When brought into the clinic the patient, to all appearances, was perfectly healthy and sane, giving the history of his trouble clearly and in detail; explaining that he had from time to time suffered from lapse of consciousness; that during these periods he seemed perfectly rational to those about him, but to himself the time was a blank, and that these periods had lasted from a few hours to several days. The history of these *absences* were as follows;

The first, it seems, came upon him in the year 1887, as he left the counting-house on some errand to the Rue de Villiere, Paris. He went his way, but lost all idea of time and place, and finally came to himself late in the evening in the Place de la Concorde, having wandered for fourteen hours. When he came to himself, he found he had the same amount of money in his pocket as in the early morning. It was plain that he had taken nothing to eat or drink during these fourteen hours.

His second attack was during the spring of 1887, when he lost all consciousness for *forty-two* hours, and awoke in the Seine, having jumped from his coupé. He was, fortunately, rescued by a policeman. It seemed that after his unconscious peregrinations he had taken a ticket upon the Railroad de Ceinture, and having passed the station where he evidently intended to get out, he had at the above time rushed from his coupé into the river. The shock of the cold water brought him again to consciousness.

A third time, in August, 1887, just as he was about to enter his own house, after business hours, he had a sudden attack of his malady, and only awoke from his living sleep after fifty-three hours, on the Pont d'Ansières, having been in fact aroused by a fisherman on the bridge, who, seeing him peering intently into the water, asked him, "What are you doing here so early?" He found himself covered with mud, and his shoes completely worn out; he had evidently been walking without interruption for nearly three days, and without food or drink.

After this last attack, recognizing that they were becoming not only more frequent but of longer duration, he consulted Charcot. The professor put him on a course of treatment, and also gave him a certificate stating that the bearer was subject to these attacks of "automatic ambulation," as he called them, and which the poor patient always carried in his pocket.

Under Charcot's handling the attacks disappeared, and all treatment was stopped. In February of this year, however, as he left one morning his place of business to make a deposit, with some 700 francs on his person, he again lost all consciousness, to awake *eight* days later, to find himself on a bridge in a strange city, which turned out to be Brest. Upon this occasion it seems that the loud music from a military band in passing close to him had called him to consciousness. Fearing himself, the poor man approached a gendarme, and told him briefly his story, adding that when he left home he had 700 francs, whereas at present he had but 500, and showing the man the certificate of Dr. Charcot. The stupid man did not, of course, understand, arrested the poor devil as a thief, or what not, and threw him into the lock-up, from which place he was finally rescued by a telegram from Professor Charcot. Since this last attack he is again under regular treatment.

This peculiar and interesting form of disease Charcot has named "l'automotisme ambulatoire," a malady in which the sufferer comes and goes, and is apparently in perfect possession of all his faculties, and yet to the man himself his every action is unknown. The writer knows of no parallel case, though he has seen almost exactly the same symptoms caused by liquor. In this latter case the man was absolutely sober, to all appearance, and perfectly rational, free from all and any of the usual effects of alcohol, and yet later he remembered nothing whatever that had passed. His friends recognized the extremely peculiar effect wine had upon him, and had always watched him most carefully.

An interesting study has lately been published in Munich on what we know as "roaring" in horses. This peculiar form of apparent dyspnœa is, it seems, caused by a paralysis of the abductor muscles of the larynx, the posterior crico-arytenoid on one side. I shall obtain a copy of the paper in Munich, and write more fully then about it.

Respectfully yours,

F. DONALDSON, JR.

STUTTGART, March 2, 1889.

BOVINE TUBERCULOSIS.

THE consideration of some plan by which the alleged injurious consequences that may result from tuberculosis in animals can be averted has recently engaged the attention of the College of Physicians of Philadelphia. If all the allegations regarding the communicability of tubercular disease to the human species by means of infected milk or flesh, are to be accepted as true, they may well excite great disquietude and even alarm. If the recommendations which were presented should be carried out, and the official inspectors proceed to execute their functions in strictest conformity to a proposed law that might condemn all animals affected with tubercular disease, the slaughter would be simply enormous, and perhaps unnecessary. On the assumption that all flesh and milk of tubercular animals are dangerous to partake of, on the other hand, there would be a general abstention from animal food and milk, as well as shrinkage of their money value.

Obviously we cannot afford to sacrifice our herds needlessly, neither should there be unnecessary alarm about the quality of the food on which we are accustomed mainly to rely. It is important therefore to ascertain whether it is practicable for an expert inspector to determine, on examination, the existence of bovine tuberculosis? Is there any liability that the milk may become contaminated during the progress, or in certain stages, of the disease? At what stage of the disease should the animal be destroyed?

During the years 1883 and 1884 an opportunity was afforded of observing an epidemic of tuberculosis which affected the herd of Holstein cows on the farm of the Willard Asylum for the Insane, in the State of New York. An interesting report upon this disease as it here occurred was made by Dr. Blaine, one of the assistant physicians who was detailed for this purpose. Attention was attracted to the herd in 1883, when it was noticed that there were many laggards which lingered behind the herd, that they were losing flesh, and had a rough coat; that they had some difficulty in breathing, and had a slight cough. On making a post-mortem the nature of the disease was discovered. On an official examination made by Prof. James Law, of Cornell University, it was found that the entire herd, numbering about 150, was affected, and on his advice all were killed, not at once, but gradually. Abundant opportunity was thus afforded of making a diagnosis in every case, which was verified by examination after death.

The results demonstrated that it was entirely practicable for an expert to make a correct diagnosis as to the existence of tuberculosis and the successive stages of the disease. The animals were slaughtered after the cervical glands were enlarged and tubercular suppuration commenced. Tubercular deposits were found in the milk bag, and a communication between the points of suppuration and the udder was demonstrated in many instances, showing how the milk might be contaminated. Before the stage of suppuration was established, examination with the lactometer showed that the milk was decidedly deteriorated. The depreciation ranged from thirty to forty per cent. in solid constituents. These facts would further go to show that it is not only practicable but important that an official inspector should have power to examine milk cows kept for dairy purposes and milk supply, and direct the removal and destruction of an animal found in advanced or suppurative stages of tuberculosis, or with a diseased milk bag.

Bovine tuberculosis usually affects the glands, lungs, liver, and organs generally, but the flesh is rarely the seat of deposit.

An examination into the condition of a large number of herds owned by farmers in the vicinity of the Asylum revealed the fact that from twenty-five to thirty per cent. were affected in various degrees, and that the disease more frequently attacked animals that were six years old or beyond that age. The cattle purchased for consumption were procured in Buffalo and brought to the Asylum, where they were slaughtered. They were known as "western cattle," and were about three or four years old. At the Asylum abattoir it was found that these animals were quite exempt from tuberculosis. No cases of active

disease were found; and only occasionally a calcified tubercle was discovered. These examinations showed a decided exemption from disease as compared with animals reared in that part of western New York contiguous to the Willard Asylum, and this fact would be established, we believe, as the result of careful observations in this vicinity.

In the epidemic which we have noticed, it was considered as established that the disease was transmitted by three imported bulls, by contact, and the ingestion of tuberculous matter while the herd was grazing. Although the Asylum community numbered about 2300, and the disease in the herd had existed for some time probably before it attracted serious attention, it was also observed that the annual mortality from phthisis had been steadily declining. NEWS ITEMS.

The Quarantine Conference, holding its session at Montgomery, Ala., adopted, March 6th, the report of its Committee on Quarantine. The report recommends that the health authorities shall regulate the hauling of persons, baggage, or freight from infected places during yellow fever epidemics, and that the regulations and restrictions shall be such as to afford protection to endangered communities; that at all seasons of the year, and under all circumstances, the simple passage of trains should be allowed, even when carrying sick refugees to other localities, and that well-digested rules to govern quarantines should be prepared, published, and enforced whenever necessary; that only competent physicians who have had experience with yellow fever should be made inspectors of quarantine stations and have power to administer oaths and detain passengers and baggage; that State boards of health should be authorized to enforce quarantine regulations; that quarantine stations at Southern seaports are of great advantage and should be continued; that ticket agents should be required not to sell tickets during the yellow fever epidemics, and that travellers shall be required to have health certificates.—*Boston Med. and Surg. Journal,* March 14, 1889.
